Pericardiocentesis

Marianne Juarez, Jacqueline Nemer

INTRODUCTION

Pericardiocentesis is the removal of fluid from the pericardial space. This is usually performed using a needle and syringe. A pericardial catheter can be placed for ongoing removal of fluid from within the pericardium. Pericardiocentesis may be performed to obtain pericardial fluid for analysis, to relieve the pressure of a pericardial effusion, to improve cardiac output, or as a lifesaving measure to relieve a cardiac tamponade. **The technique is relatively simple to perform yet has a significant rate of complications.¹**

Penetrating chest injuries and their subsequent outcomes have been described in the romantic and medical literature for centuries. Cardiac tamponade was first described by Riolanus as early as 1649, with pericardiocentesis described in 1827 by Thomas Jowett as an intervention for pericarditis.²⁻⁹ In 1829, Baron Larrey, Napoleon's Surgeon, is reported to have performed the first successful pericardiocentesis.⁶ By 1939, Bigger had suggested that some patients with cardiac tamponade could be managed with pericardial tubes alone with prompt operation for recurrence.⁸

ANATOMY AND PATHOPHYSIOLOGY**ANATOMY OF THE HEART AND PERICARDIUM**

The pericardium is an inverted cone-shaped sack surrounding the heart that sits atop the diaphragm (**Figure 48-1**).¹⁰ The inner portion, or visceral pericardium, is a single layer of mesothelial cells covering the epicardium. The outer layer is composed of a dense outer fibrous tissue with an inner layer of mesothelial cells known as the parietal pericardium. The fibrous pericardium is attached to the central tendinous portion of the diaphragm inferiorly. The outer fibrous layer blends superiorly with the sheath covering the great vessels. It attaches anteriorly to the posterior surface of the sternum.

It is attached posteriorly to the thoracic vertebral column, esophagus, bronchi, and aorta.

The pericardial cavity is a potential space between the visceral and parietal layers of the pericardium. It normally contains up to 50 mL of fluid that acts as a lubricant to the motion of the heart.¹¹ There are a variety of conditions that result in excess fluid in the pericardial space, which require drainage. The estimated causes and relative frequencies of pericardial effusions are listed in **Table 48-1**.¹²⁻¹⁸

The heart is contained within the pericardial sac (**Figure 48-1**). Numerous portions of the heart are exposed behind the anterior chest wall (**Figure 48-2**) and are vulnerable to injury that may result in a pericardial effusion or cardiac tamponade.¹⁹⁻²¹ The surface area that each of these structures contributes to the anterior cardiac silhouette and a general estimate as to the incidence of injury are based on the anatomic structure as listed in **Table 48-2**.^{19,22}

PATHOPHYSIOLOGY OF CARDIAC TAMPONADE

The clinical effects of cardiac tamponade occur due to accumulation of fluid under pressure in the pericardial space. This space can become quite large over time in several chronic conditions and contain pericardial effusions up to 2 L without signs of cardiac tamponade.^{14,23} The pericardial sac has a very limited ability to stretch in the acute setting if the pericardial fluid volume changes rapidly. This results in an increase in fluid pressure surrounding the heart and possible cardiac tamponade. Cardiac tamponade can be caused acutely by accumulation of pericardial fluid ranging from 60 to 200 mL.^{11,24}

The pressure-volume relationship between the size of the pericardial effusion and the pressure imposed on the cardiac chambers becomes exponential in the acute setting. The initial accumulation of fluid produces little or no clinical effect. The initial physiologic strategies of compensation include an increase in the systemic venous pressure, catecholamine release, and tachycardia. Small increases in the fluid amount will generate significant and increasing pressure on the heart chambers once the ability of the pericardial space to distend and accommodate more fluid is overwhelmed. Venous filling of the right heart is drastically impaired as the pericardial pressure rises. The interventricular septum bulges into the left ventricle. Left ventricular filling becomes compromised from the lack of flow from the right ventricle and the bulging inward of the interventricular septum. Cardiac perfusion eventually decreases, the heart contractility is progressively impaired, and the patient becomes hypotensive.

A progressive decline in cardiac output occurs as pericardial fluid accumulates and intrapericardial pressure increases.²⁵ The right atrial pressure is initially greater than the intrapericardial pressure as the body compensates by increasing venous return. This is followed by the equilibration of the right atrial and intrapericardial pressures. The heart chambers eventually cannot achieve a pressure lower than the surrounding pericardial fluid pressure. Equilibration of diastolic pressure in each heart chamber occurs and produces the greatest drop in cardiac output. The cardiac chambers collapse as the intrapericardial pressure continues to increase. This results in intractable hypotension and death.

There is a disproportionate effect of the accumulation of small amounts of fluid in this late stage. The patient can proceed from stable and compensated to profoundly unstable quite suddenly. It is dangerous to rely on central venous pressure line monitoring alone to recognize the evolution of cardiac tamponade. It can produce dramatic temporary improvements in the clinical status of the patient if treated by the withdrawal of a small amount of fluid from the pericardial cavity.

Cardiac tamponade is a life-threatening condition that must be diagnosed and treated emergently. It may easily be overlooked

unless a high index of suspicion is maintained in medical and trauma patients. Pericardial effusions and tamponade may occur in several medical conditions (e.g., anticoagulant use, coagulopathies, congestive heart failure, connective tissue disease, drug side

TABLE 48-1 The Etiologies and Relative Frequencies of Pericardial Effusions

Etiology	Relative frequency (%)
Cancer	15–40
Connective tissue diseases	2–11
Idiopathic	13–14
Infectious (including HIV)	2–14
Postpericardiotomy	2–16
Radiation therapy	4–7
Trauma	7–9
Uremia	5–10

Source: Adapted from references 12–18.

effects, endocrine disease, infections, inflammatory bowel disease, malignancies, mediastinitis, postmyocardial infarction syndrome, postpericardiotomy syndrome, radiation therapy, and uremia).^{21,26–38} Cardiac tamponade can be a complication of procedures (e.g., cardiac surgery, coronary intervention, electrophysiologic study with intracardiac electrodes, myocardial biopsy, pacemaker lead extraction, radiofrequency ablation, and transvenous pacemaker placement).^{21,31,39–42} Cardiac tamponade may be sudden and painful due to hemopericardium from myocardial free wall rupture after myocardial infarction, posttraumatic aortic dissection, rupture of the ascending aorta, or spontaneous aortic dissection.^{20,34,43–45}

Sauer and Murdock describe a “danger zone” for penetrating torso trauma (**Figure 48-3**).⁴⁶ The superior border is bounded by a line through the sternal notch. The lateral borders are bound by the mid-clavicular lines. The inferior border is identified by a line through the epigastric area. Any penetrating injury involving the “danger zone” has the potential to cause a cardiac injury and cardiac tamponade.

FIGURE 48-2. View of the heart and great vessels that can become injured behind the anterior chest wall. AO, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

PATIENT EVALUATION

Several clinical findings are associated with cardiac tamponade. **Beck's triad of muffled heart sounds, hypotension, and jugular venous distention is associated with cardiac tamponade. The minority of patients with cardiac tamponade will have all three of the Beck's triad conditions.** Most patients with cardiac tamponade may have at least one of the findings in Beck's triad. Restlessness, fatigue, tachycardia, and tachypnea are often present in cardiac tamponade. **Cardiac tamponade must always be considered as a potential cause of shock in the hypotensive patient. Findings may be subtle or absent if the patient is hypovolemic.** Cardiac tamponade may progress to shock, coma, and death. The differential diagnosis includes acute myocardial infarction, cardiac shock, constrictive pericarditis, hypothermia, pneumothorax, and pulmonary embolism.

The systolic blood pressure (SBP) lowers with inspiration compared to expiration with the difference of less than 10 mmHg in normal physiology. **Pulsus paradoxus is a drop in SBP of ≥ 10 mmHg during inspiration compared to expiration.** Pulsus paradoxus can be present in conditions that limit heart filling (e.g., accumulation of pericardial fluid, constrictive pericarditis, and increased intrathoracic pressures from lung disease). Inflate the blood pressure (BP)

TABLE 48-2 Structures Vulnerable to Injury Behind the Anterior Chest Wall	
Anatomic structure	%*
Right ventricle	55
Left ventricle	20
Right atrium	10
Left atrium	1
Aorta and pulmonary artery	10
Inferior vena cava	4

FIGURE 48-3. The “danger zone” for penetrating chest trauma.⁴⁶

cuff until the cuff pressure is greater than the patient's SBP and then slowly release the cuff pressure while auscultating until heart beats are heard only during expiration. Continue deflating the cuff pressure until heart beats are heard continuously in both inspiration and expiration. **Pulsus paradoxus is the difference between these two cuff pressures (Figure 48-4).**⁴⁷

Kussmaul's sign is the paradoxical increase of the jugular venous pressure (JVP) during inspiration instead of the normal decrease in JVP with inspiration. This usually indicates impaired right heart filling. It may be due to myocardial impairment, pericardial fluid, or restriction of the pericardium.

Traumatic cardiac tamponade can be caused by a variety of agents and etiologies. This includes central venous line placement, displaced fractured ribs, intracardiac injection, migrating pins or needles, pacemaker insertion, penetrating thoracic injuries, pericardiocentesis, surgery, and venous bullet embolization. **Cardiac tamponade is the most common presentation of penetrating cardiac**

FIGURE 48-4. US apical four-chamber view with the Doppler sample gate placed at the tip of the mitral valve leaflets. Variation of the E wave is noted over the respiratory cycle with the lowest and highest velocities recorded as A and B, respectively. The difference between the two (36.2 cm/s and 67.6 cm/s) is 54%. Greater than 25% difference represents sonographic pulsus paradoxus. (Photo used with permission from reference 47.)

FIGURE 48-5. Subxiphoid ultrasound window demonstrating the four-chamber view (RV, right ventricle; LV, left ventricle; RA, right atrium; LA, left atrium) of a heart with a pericardial effusion (asterisks). The liver is noted anterior to the heart. The arrows point to the posterior pericardium.

injuries overall and must be considered in all trauma patients with penetrating trauma and hypotension.²²

Bedside cardiac ultrasound (US) has become the diagnostic procedure of choice to identify cardiac tamponade.⁴⁷⁻⁴⁹ Bedside US can rapidly confirm a suspected pericardial effusion or cardiac tamponade (**Figure 48-5**). US can be used to guide drainage.⁴⁸ Blind pericardiocentesis has a high complication rate and a high mortality rate.^{15,16,50} US-guided pericardiocentesis can decrease the rate of complications by allowing visualization and avoidance of adjacent anatomic structures. This increased safety factor is supported by multiple studies.^{46,50-60}

US features that suggest cardiac tamponade are noted in **Table 48-3**. This includes circumferential pericardial effusion (**Figure 48-6**), dilatation of the inferior vena cava (IVC) without respiratory variation (e.g., IVC that collapses > 50% with inspiration or a forced sniff

FIGURE 48-6. Pericardial tamponade with right ventricular collapse (arrowhead). A large pericardial effusion (asterisks) is visible. Arrows point to the posterior pericardium. AO, aortic root; LA, left atrium; LV, left ventricle; RV, right ventricle.

maneuver), right atrial systolic collapse, and right ventricular diastolic collapse (**Figure 48-6**).

Evaluate the IVC by placing the US probe in the subxiphoid region, with the probe marker pointing toward the patient’s head. The IVC runs parallel with and to the right of the aorta. Use M-mode to measure the diameter of the IVC approximately 2 cm from the right atrium. The normal IVC ranges from 1.5 to 2.5 cm in diameter and displays respiratory variation. **The IVC is dilated, measures > 2.5 cm in diameter, and does not display respiratory variation in cardiac tamponade.** Some authors advocate using transesophageal echocardiography, even in unstable patients, because of its superior imaging when compared to transthoracic echocardiography.¹⁸ Other methods of imaging the pericardium include computed tomography (CT), helical CT, and magnetic resonance imaging. **Use these for stable patients when assessing for a pericardial effusion and not cardiac tamponade.**⁶¹

Cardiac tamponade may not be identified by electrocardiogram (ECG) or plain radiographic findings. ECG findings are not diagnostic but may be present in patients with a significant pericardial effusion or cardiac tamponade. A large pericardial effusion can result in a “low-voltage” ECG tracing. **Electrical alternans is a change in the morphology or amplitude of the QRS complexes on the ECG as the heart swings back and forth within the pericardial fluid (Figure 48-7).**^{62,63} It may be associated with either cardiac tamponade or a large pericardial effusion. Pulseless electrical activity (PEA) in the absence of hypovolemia or a tension pneumothorax is highly suggestive of cardiac tamponade. The finding of an enlarged cardiac silhouette on a chest radiograph may be useful in chronic pericardial effusions but is usually absent or nonspecific in the acute setting.

INDICATIONS

The only indication for emergent pericardiocentesis is the presence of life-threatening physiologic changes of cardiac tamponade, and the diagnosis is consistent with known prior disease, traumatic injury, or an US.⁶⁴⁻⁶⁶ A pericardiocentesis can be used in penetrating trauma to “buy time” until definitive surgical care.^{66,67} Use bedside US if available to demonstrate a pericardial effusion and/or cardiac tamponade. A pericardiocentesis may be performed in a cardiac arrest patient with PEA when other etiologies for PEA have been

TABLE 48-3: US Findings of Cardiac Tamponade	
Ultrasonographic mode	Findings
Doppler	Mitral flow decreases during inspiration
	Mitral flow increases during expiration
	Tricuspid flow increases during inspiration
	Tricuspid flow decreases during expiration
	Peripheral flow decreases in expiration
M-mode color Doppler	Mitral flow decreases during inspiration
	Mitral flow increases during expiration
	Tricuspid flow increases during inspiration
	Tricuspid flow decreases during expiration
M-mode/two-dimensional	Diastolic collapse of the right ventricular free wall
	Inferior vena cava dilation
	Inferior vena cava does not collapse on inspiration
	Increase left ventricular wall thickness in diastole
	Left atrial collapse
	Left ventricular collapse
	Right atrial collapse
	Swinging heart to and fro

FIGURE 48-7. ECG of electrical alternans. **A.** Initial ECG showing electrical alternans. Bedside US revealed a large pericardial effusion with right ventricular diastolic collapse. **B.** Resolution of electrical alternans after pericardiocentesis.

ruled out or a pericardial effusion is seen on US. Pericardiocentesis may be performed to obtain pericardial fluid for diagnostic testing.

CONTRAINDICATIONS

There are no absolute contraindications to performing an emergent pericardiocentesis in the unstable patient with signs of cardiac tamponade. Any uncorrected anticoagulation from medications or

a bleeding disorder will be an absolute contraindication to performing the procedure in a stable patient. Small, loculated, or posteriorly located effusions in a stable patient are considered contraindications. Pericardiocentesis is contraindicated in cardiac tamponade associated with myocardial free wall rupture after myocardial infarction, spontaneous aortic dissection, posttraumatic aortic dissection, or rupture of the ascending aorta.⁶⁸ These are surgical emergencies that require prompt diagnosis and surgery. There is conflicting research

regarding whether these should be treated by needle pericardiocentesis initially. Some reports note the pressure of the intrapericardial blood opposes further bleeding. The removal of pericardial fluid reduces the pressure and may cause further bleeding to occur, often with fatal results.^{20,68} Other research reports successful management of type A aortic dissection by pericardial drainage.⁵⁸

Many authors feel there is little to no role for pericardiocentesis in the trauma patient. These authors argue that once the diagnosis is made, the patient should receive a prompt thoracotomy.⁶⁹ An Emergency Department thoracotomy (Chapter 54) should be performed if the patient is too unstable for transport to the Operating Room for a formal thoracotomy.

EQUIPMENT

■ PERICARDIOCENTESIS

- Povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask with eye shield or goggles
- 1% lidocaine solution
- 25 gauge needle, 5/8 inch long
- 18 gauge needle, 1½ inches long
- Syringes (10, 20, and 60 mL)
- Sterile drapes
- Towel clips
- 16 to 18 gauge spinal needle or catheter-over-the-needle, 7.5 to 12.5 cm long
- 18 to 20 gauge spinal needle or catheter-over-the-needle, 3.75 cm long
- #11 scalpel blade
- 4 × 4 gauze squares
- Alligator clips connected by a wire
- Collection basin
- ECG monitor
- J-tipped guidewire, 0.035 mm in diameter
- Size 6 to 10 French flexible multihole catheter, 5 to 6 inches long, with or without a pigtail

- Three-way stopcock
- Plastic tubing
- US machine
- 3.5 to 5.0 MHz phased-array or curvilinear US transducer
- Sterile US transducer cover (can be a sterile glove)
- Sterile US gel
- Variable-angle needle guide attachment, if available
- Nasogastric tube

■ SUBXIPHOID PERICARDIAL WINDOW

- Electrocautery set
- Forceps
- Small retractor
- Small rib spreaders
- Sutures, 2-0 Vicryl and 3-0 nylon
- Sterile suction device
- Yankauer suction catheter
- Suction tubing

It is important to become familiar with the supplies available in the Emergency Department. Some Emergency Departments may not have single guidewires and flexible catheters readily available to use for a pericardiocentesis. Commercially produced pericardiocentesis kits are available from numerous manufacturers and contain the required equipment (**Figure 48-8**). A 6 to 10 French single-lumen central venous line access kit may be substituted in an emergency.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative if the patient's clinical condition permits. Place the signed consent in the medical record. A signed consent is not mandatory if this is an emergent procedure. Document the reason for not obtaining written consent in the medical record. Position the patient semirecumbent at a 30° to 45° angle (**Figure 48-9**) if no contraindications exist. This position brings the heart closer to the anterior chest wall. The supine position is an acceptable alternative.

A

B

FIGURE 48-8. Some of the commercially available pericardiocentesis kits. **A.** Cook Medical, Bloomington, IN. **B.** Boston Scientific, Marlborough, MA.

FIGURE 48-9. Ideal patient positioning for performing a pericardiocentesis.

Apply cardiac and BP monitoring, pulse oximetry, and supplemental oxygen. The placement of an arterial line may be helpful for additional monitoring (Chapter 72). An arterial line is not necessary and should not delay the pericardiocentesis. **Insert a nasogastric tube to decompress the stomach and decrease the possibility of gastric perforation by the pericardiocentesis needle (Chapter 75).**

Identify the anatomic landmarks necessary to perform this procedure. The needle can be inserted at numerous sites (**Figure 48-10**). These include below the xiphoid process, at the right sternocostal margin, at the left sternocostal margin (i.e., subxiphoid approach), in the left or right fifth intercostal space parasternally (i.e., parasternal approach), or in the left fifth intercostal space at the midclavicular line (i.e., apical approach). The most commonly used site is at the left sternocostal margin (i.e., subxiphoid approach) if bedside US is not available. This is the approach described throughout the “Techniques” section of this chapter.

Surgically prepare the parasternal and subxiphoid areas. Clean any blood, dirt, and debris from the area. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to delineate a sterile surgical field. Reidentify the anatomic landmarks and confirm them by bedside US if available. Anesthetize the needle tract with local anesthetic solution if the patient is awake. Place a subcutaneous wheal of local anesthetic solution at the site chosen to insert the needle. Inject local anesthetic solution through the skin wheal and into the subcutaneous and deeper tissues of the thoracic wall.

FIGURE 48-10. Potential sites to perform a pericardiocentesis.

Aseptic technique must be followed even though this is an emergent procedure. Don full personal protective equipment (i.e., hat, mask, sterile gown, and sterile gloves). Prepare the equipment. Set up a sterile field on a bedside table. Open all required equipment and place it on the sterile field. Connect the spinal needle to a 20 mL syringe containing 5 mL of sterile saline. Prepare all the supplies prior to prepping the patient. Attach a three-way stopcock between the syringe and spinal needle. The stopcock will facilitate the removal of fluid. Attach intravenous extension tubing to the stopcock.

TECHNIQUES

BLIND INSERTION TECHNIQUE

Puncture the skin with a #11 scalpel blade between the xiphoid process and the left costal margin. Grasp the syringe with the dominant hand. Insert the spinal needle through the skin incision and at a 45° angle to the midsagittal plane (**Figure 48-11A**) and at a 45° angle to the abdominal wall (**Figure 48-11B**). Aim the tip of the spinal needle toward the patient's left shoulder (**Figure 48-11A**). The spinal needle can be alternatively aimed toward the patient's left mid-clavicle, right mid-clavicle, or sternal notch to theoretically lessen the chance of iatrogenic damage to the coronary arteries.

Advance the spinal needle 4 to 5 cm while applying negative pressure to the syringe and observing the cardiac monitor. Inject 0.25 to 0.50 mL of saline occasionally to ensure that the needle remains patent while advancing. Continue advancing the spinal needle while applying negative pressure until there is a return of blood, cardiac pulsations are felt, or there is an abrupt change in the ECG waveform. **Stop advancing the needle and withdraw it in 1 to 2 mm increments until the ECG pattern normalizes if the ECG waveform shows an injury pattern (i.e., ST-segment elevation or ventricular arrhythmia).** ECG changes indicate that the needle is touching or has penetrated the myocardium.

Aspirate with the syringe. A large volume of blood that is quickly and easily withdrawn may indicate that the tip of the spinal needle is within the ventricle. Slowly withdraw the needle while aspirating if there is a suspicion that the needle has entered the ventricle and bedside US is not available. The aspiration of free-flowing blood will stop as the needle passes through the ventricular wall. Aspirate the pericardial fluid when the needle enters the pericardial space.

Techniques to confirm the intraventricular placement of the needle tip have been described. These include observing that the aspirate does not form a clot, comparing the venous hemoglobin to that of the aspirate, injecting fluorescein and looking for a fluorescein flush under the eyelid skin, or injecting 3 mL of dehydrocholic acid (i.e., Decholin) and asking whether the patient experiences a bitter taste.⁷⁰ These are time consuming and less reliable than US, if available.

There will be a marked improvement in hemodynamics and clinical status when the pericardial space is entered and fluid is aspirated. The procedure can be terminated once the patient's hemodynamics have improved.

The Emergency Physician may choose to withdraw as much fluid as possible. Stop withdrawing the plunger when the syringe is filled with fluid. Stabilize the spinal needle against the patient's torso and remove the syringe. Attach a new syringe to the spinal needle and continue the procedure. The epicardium will approach the needle tip as the pericardial space is drained. Slowly withdraw the needle 2 to 3 mm if an injury pattern appears on the cardiac monitor. It will return to baseline. Continue to aspirate fluid. Remove the needle when fluid can no longer be aspirated.

Alternatively, attach a three-way stopcock between the spinal needle and the syringe. Attach intravenous extension tubing to the

FIGURE 48-11. The subxiphoid approach. The needle is inserted at a 45° angle to the midsagittal plane (A) and at a 45° angle to the abdominal wall (B). The alligator clip attached to the spinal needle is for the ECG-monitored technique and not the blind technique.

stopcock. An assistant can open and close the stopcock while the Emergency Physician aspirates fluid and ejects it through the extension tubing into a basin. The epicardium will approach the needle tip as the pericardial space is drained. Slowly withdraw the needle 2 to 3 mm if an injury pattern appears on the cardiac monitor. It will return to baseline. Continue to aspirate fluid. Remove the needle when fluid can no longer be aspirated.

ECG-MONITORED TECHNIQUE

The purpose of ECG monitoring is to prevent accidental ventricular puncture with the spinal needle. It is not necessary with the US-guided technique. Attach one alligator clip to the base of the spinal needle and the other to the V₁ lead of the ECG machine or cardiac monitor (Figure 48-12). The V₁ lead will serve as an active electrode based at the tip of the spinal needle. An injury pattern noted by ST-segment elevation will be seen if the myocardium is contacted or

penetrated by the spinal needle. The presence of a premature ventricular contraction or a ventricular arrhythmia can signify contact with the myocardium.

Prepare the patient as previously described. Prepare the equipment (Figure 48-12). Turn on the ECG machine or cardiac monitor. Insert and advance the spinal needle, as described previously, while observing the ECG monitor or cardiac monitor. Slowly withdraw the needle in 1 to 2 mm increments if an injury pattern or premature ventricular complexes are seen. Continue to withdraw the needle in 1 to 2 mm increments until the injury pattern resolves. Aspirate the pericardial fluid as described in the preceding section.

SELDINGER TECHNIQUE

An indwelling catheter may be placed in the pericardial cavity to drain the pericardial fluid (Figure 48-13). This may be done in cases of medical or traumatic pericardial effusions since the pericardial fluid often reaccumulates. An indwelling catheter allows intermittent drainage of pericardial fluid without the potential complications associated with repeated needle sticks from a pericardiocentesis. This procedure can “buy time” if an Operating Room and/or Surgeon is not immediately available to perform a pericardial window.⁶⁶

The technique is similar to that of placing an indwelling central venous line. Clean and prepare the patient. Insert the spinal needle by US guidance, blindly, or with ECG monitoring as described in the previous sections (Figure 48-11). Aspirate to confirm that the tip of the spinal needle is within the pericardial cavity (Figure 48-13A). **It is imperative that the tip of the spinal needle be within the pericardial cavity and not within the cardiac chamber. The position of the needle must be verified by one of the methods described in the section on “Blind Insertion Technique,” by fluoroscopy, or by US if intracardiac placement of the needle is suspected.**

Grasp and stabilize the spinal needle with the nondominant hand. Gently remove the syringe from the spinal needle with the dominant hand. Insert the guidewire through the needle and into the pericardial cavity (Figure 48-13B). Advance the guidewire until approximately one-third of its length is within the patient. Stabilize the guidewire with the nondominant hand. Remove the needle over

FIGURE 48-12. Equipment preparation for the ECG-monitored technique.

FIGURE 48-13. The Seldinger technique. **A.** The spinal needle is inserted into the pericardial space. **B.** The guidewire is inserted through the needle. **C.** The needle has been removed and the guidewire remains within the pericardial cavity. **D.** The dilator is advanced over the guidewire to dilate the needle tract. **E.** The catheter is advanced over the guidewire. **F.** The guidewire has been removed and the catheter remains within the pericardial cavity.

the guidewire while leaving the guidewire within the pericardial cavity (**Figure 48-13C**).

Continue to stabilize the guidewire with the nondominant hand. Advance the dilator over the guidewire and into the pericardial cavity (**Figure 48-13D**). **Dilating a tract through the myocardium can result in cardiac tamponade and/or exsanguination if the guidewire is within the heart. It is imperative to know that the guidewire is within the pericardial cavity and not within the heart.** Remove the dilator while leaving the guidewire within the pericardial cavity. Advance the soft multihole catheter over the guidewire and into the pericardial cavity (**Figure 48-13E**). Remove the guidewire while leaving the catheter within the pericardial cavity (**Figure 48-13F**). Secure the catheter at the skin with the nondominant hand. Attach a syringe to the catheter and aspirate pericardial fluid. This should cause a rapid improvement in the patient's clinical status. Detach the syringe and attach a three-way stopcock to the catheter.²³ Secure the catheter to the skin with nylon sutures.

US-GUIDED TECHNIQUE

Many authors feel that US-guided pericardiocentesis is now the standard of care.^{14,23,61,71-73} The heart is best scanned with the

patient in a semierect or left lateral position if no contraindications exist. Use the 3.5 to 5.0 MHz phased array or curvilinear US transducer. Examine the heart and pericardial space in two-dimensional and Doppler mode to determine the extent of the pericardial effusion and the area with the largest fluid collection.^{74,75} This is usually located around the apex of the heart.

View the heart and pericardial space using the three standard cardiac US views. These are the subxiphoid or subcostal view, the parasternal long axis view, and the apical four-chamber view (Chapter 37). Pericardial fluid is anechoic, appears black on US, and will collect in a dependent location if adhesions are not present. Small pericardial effusions will first be seen in the posterior pericardium. Large pericardial effusions appear circumferential and extend around the heart.

The decision to use a parasternal (**Figure 48-14**) or an apical (**Figure 48-15**) window depends on which US views of the pericardial effusion and heart can be obtained. **The ideal site is where the pericardial effusion is most superficial, has a large stripe or thickness, and where no other structures (e.g., lung or liver) are in the path from the skin to the heart.**^{60,76} The subxiphoid window (**Figures 48-5 and 48-16**) is not recommended for US-guided pericardiocentesis. This view commonly includes the left lobe of

FIGURE 48-14. Phased-array probe placed in the left parasternal window adjacent to the sternum, between the second and fourth intercostal spaces. The probe marker is pointing to the patient's left hip.

the liver in the anterior portion of the US image. The pericardiocentesis needle might puncture the liver on the way into the pericardial cavity.

There are established US findings that help to distinguish a pericardial effusion from a cardiac tamponade (**Figure 48-6** and **Table 48-3**).⁶⁸ These include right ventricular diastolic collapse (**Figure 48-6**), right atrial systolic collapse, large pericardial effusion, and dilatation of the IVC. Place the US transducer in the subxiphoid region with the transducer marker pointing toward the patient's head. The IVC will be seen running parallel to the aorta and to the right of the aorta. Use M-mode to measure the diameter of the IVC. The normal IVC ranges from 1.5 to 2.5 cm in diameter and displays respiratory variation (**Figure 48-17A**).^{77,78} The IVC is dilated, measures > 2.5 cm in diameter, and does not display respiratory variation (**Figure 48-17B**).^{77,78}

Position the patient. Determine the location to perform the pericardiocentesis. Clean, prep, and drape the patient as described

FIGURE 48-15. A phased-array probe placed in the apical window at the point of maximal impulse (PMI). The probe marker is pointing to the patient's right.

FIGURE 48-16. A curvilinear probe placed in the subxiphoid region. The probe is aimed toward the patient's left shoulder. The probe marker is pointing to the patient's right. Note the shallow angle required to visualize the heart.

FIGURE 48-18. Ultrasound probe and the pericardiocentesis needle in the apical window.

previously. Apply a sterile transducer cover. Apply sterile US gel over the covered transducer. Reidentify and confirm the proper US transducer position.⁷⁶ This is usually the point where the pericardial effusion is closest to the chest wall.^{74,75} Insert the spinal needle under US guidance into the chest wall (**Figure 48-18**). Insert the needle over the superior border of the rib to avoid the neurovascular intercostal bundle under the inferior edge of the rib. Aspirate as the needle tip is carefully advanced under direct US visualization into the pericardial space (**Figure 48-19**).

Use agitated saline to confirm proper needle placement if there is any question as to whether the needle tip is in the pericardial space or if bloody fluid is aspirated (**Figure 48-20**).^{74-76,79,80} This requires two 5 mL syringes, one filled with sterile saline and the other filled with air. Attach the syringes to a three-way stopcock. Rapidly move the sterile saline back and forth between the two syringes and create an aerated saline solution. Rapidly inject the aerated solution through the spinal needle. The identification of hyperechoic “bubbles” on the US image confirms the location of the needle (**Figure 48-20**). An alternative to this technique is to use color Doppler to localize the needle tip.^{81,82}

A

FIGURE 48-20. US image of agitated saline in the pericardial sac.

SUBXIPHOID PERICARDIAL WINDOW

The Emergency Physician may decide to place a pericardial window in very rare situations.⁸³⁻⁸⁵ **This procedure should only be performed by an Emergency Physician trained and skilled in this procedure.** A pericardial window will minimize false-negative results seen with cardiac tamponade from myocardial injury by the pericardiocentesis needle, iatrogenic bleeding, and a pericardiocentesis. Prepare the patient as previously described. Inject local anesthetic solution subcutaneously from the xiphoid process across the confluence of the lower ribs and 6 cm down the midline (**Figure 48-21A**). Inject local anesthetic solution into the muscular layers in the midline over the xiphoid process and continue approximately 8 cm inferiorly.

Make a midline longitudinal incision from the xiphisternal junction to about 8 cm below the tip of the xiphoid process (**Figure 48-21A**). Incise down to the linea alba. Bluntly dissect the space behind the xiphoid and lower sternum to separate the anterior diaphragm from the sternum. Lift the lower sternum with a retractor (**Figure 48-21B**). Use an electrocautery unit, if available, for

B

FIGURE 48-21. The pericardial window. **A.** The site of the skin incision. **B.** The xiphoid and sternum are lifted upward to expose the pericardium. An incision is made and a piece of the pericardium is removed. **C.** A chest tube is inserted into the pericardial space to allow continuous drainage of fluid.

hemostasis. Bluntly divide the fatty tissue and retrosternal attachments of the diaphragm to reveal the pericardium beneath the angle of the xiphoid and the left costal margin.⁸⁶ It will often appear blue in color due to underlying blood.

Grasp the pericardium with forceps. Incise the pericardium with a scissors or with shallow strokes of a scalpel (**Figure 48-21B**). Fluid should rush out rapidly. Remove a piece of the pericardium to make sure that it remains open (**Figure 48-21B**). Gently explore the pericardial space digitally and with the suction catheter to remove any clot and fluid. Allow the skin to stay open and permit the free drainage of the pericardial space.

Alternatively, place a 28 French chest tube in the pericardial space and secure it with a purse-string suture through the fibrous pericardium (**Figure 48-21C**). The chest tube may exit the skin incision or a separate incision in the skin. Attach the chest tube to a suction source. Close the linea alba with interrupted 2–0 Vicryl sutures. Close the subcutaneous tissue and skin with 3–0 nylon sutures.

ALTERNATIVE TECHNIQUES

CATHETER-OVER-THE-NEEDLE TECHNIQUE

A long catheter-over-the-needle (i.e., angiocatheter) mounted on a syringe may be used instead of a spinal needle mounted on a syringe.

Use a 16 to 18 gauge, 7.5 cm or longer catheter-over-the-needle for older children, adolescents, and adults. Use an 18 to 20 gauge, 3.75 cm catheter-over-the-needle for infants and small children. The procedure is the same as using a spinal needle up to the point of the needle entering the pericardial space. Stop advancing the catheter-over-the-needle once the pericardial space is entered. Securely hold the syringe so it does not move inward or pull outward. Advance the catheter over the needle and into the pericardial cavity. Continue to advance the catheter until its hub is against the skin. Securely hold the catheter hub against the skin. Remove the syringe and needle as a unit. Attach a 20 mL syringe or a stopcock to the catheter hub and aspirate. The remainder of the procedure is as described previously.

ALTERNATIVE APPROACHES

The subxiphoid approach is the classic or traditional approach and has been described previously. The use of US is changing the technique to a more apical approach.^{59,79} This area tends to be closer to the anterior chest wall and where the pericardial effusion is the largest. The use of US makes the procedure easier to perform.

The blind technique can be performed using the parasternal, intercostal, or periapical approaches. It was previously recommended to insert the needle perpendicular to the skin and 3 to 4 cm lateral to the sternum for the parasternal approach to avoid the

internal mammary artery. Needle insertion just lateral to the sternal border will avoid the internal mammary artery.⁸⁷ Do not use the intercostal approach blindly as it increases the risk of lung penetration by the needle and a subsequent pneumothorax. A blind apical approach is not recommended. The lingula of the left lung and the pleural space are close to this site. Penetration of the lingula can result in a pneumothorax.

ASSESSMENT

The lack of blood return does not rule out the diagnosis of cardiac tamponade. False-negative aspirations from a pericardiocentesis are well documented and are described at rates as high as 80%.⁸⁸ The occurrence of false-negative aspirations is often due to clotted blood in the pericardial space that cannot be aspirated or from failure to enter the pericardial space.

A dramatic improvement in the patient's clinical status should be observed after the successful drainage of the pericardial space. The patient's blood pressure and cardiac output should increase while intracardiac pressure and intrapericardial pressure decrease. Obtain a chest radiograph after the procedure to rule out a hemothorax and/or pneumothorax. Obtain an ECG to look for changes consistent with coronary artery injury from the needle.

A pericardiocentesis is often performed in the nontraumatic medical patient. Send the pericardial fluid in these cases for chemical, cytologic, and microbial analyses to determine the etiology of the pericardial effusion. Laboratory analysis should include the appearance of the fluid, a cell count and differential, glucose level, lactate dehydrogenase (LDH) level, pH, and total protein level. Cytology may reveal a malignant etiology of the effusion. The microbiology lab should perform an acid-fast stain, aerobic and anaerobic bacterial cultures, fungal cultures, Gram stain, and viral cultures.

AFTERCARE

If a catheter was placed in the pericardial space, secure it with sutures to the skin and check for stability. Consult a Surgeon for definitive care of trauma patients if not already done. Prepare these patients for rapid transport to the Operating Room. Monitor patients for reaccumulation of pericardial fluid and for hemodynamic instability. Repeat the procedure or open the stopcock if placed to reaspirate the pericardial space if fluid reaccumulates. Flush with sterile saline after each aspiration to maintain the patency of the catheter. Consult a Thoracic Surgeon if purulent fluid is aspirated in medical patients. Admit all patients to an Intensive Care Unit for further monitoring, evaluation, and treatment.

COMPLICATIONS

Blind pericardiocentesis complication rates vary from 4% to 40%.^{14,52,89} The complication rates of US-guided aspirations have been reported to be less than 5%.¹⁴ Reaccumulation of pericardial fluid may occur in up to 70% of blind aspirations.¹¹ Continuous drainage with a pericardial catheter can reduce this to 25%.¹¹ Potential complications include bleeding, decline or death as a result from recurrence or occurrence of tamponade, dysrhythmias, hemoperitoneum, hemothorax, injury (e.g., myocardium, coronary arteries, pericardial vasculature, internal mammary vessels, liver, lung, or gastrointestinal tract), and/or pneumothorax by the spinal needle.⁹⁰

Do not rock the spinal needle or change its direction once it is inserted into the patient to minimize injury. Penetration of the myocardium can result in asystole, dysrhythmias, ventricular fibrillation, or ventricular tachycardia. False-negative aspirations (i.e., a dry tap) occur if the blood in the pericardial cavity is clotted or if the needle is not within the pericardial cavity. False-positive aspirations

may be seen if the needle is within the heart chamber or a vascular structure. Hepatic damage may lead to bile leakage or blood in the abdominal cavity. A vasovagal reaction can occur if the patient is awake.

Air can be introduced into the pericardium.^{42,91,92} This is especially true if a catheter is left in the pericardium. This is a rare complication from pericardiocentesis. The etiology of the air is the creation of a communication from the pleura or air leakage around the catheter. This is visible as air in the pericardium on US. Cardiac tamponade from air can occur if enough air enters the pericardial cavity.

Pericardiocentesis can rarely result in paradoxical hemodynamic instability or the pericardial decompression syndrome.⁹³⁻⁹⁵ The patient develops cardiac shock after the pericardiocentesis. The mortality is high for this complication. The etiology is hypothesized but unknown. The drainage of pericardial fluid relieves the pressure on the right ventricle, leads to an increased preload, and combines with increased systemic vascular resistance to cause left ventricular overload. Another theory is the myocardial stunning and hibernation due to the pericardial fluid causing increased pressure and collapse of the coronary arteries. This results in biventricular failure or cardiogenic shock with either etiology.

SUMMARY

Pericardiocentesis is an infrequently performed procedure. It can be lifesaving when a patient has a cardiac tamponade. The procedure is relatively simple yet has a significant rate of complications, morbidity, and mortality. The use of bedside US to assist in making the diagnosis and in guiding the placement of the pericardiocentesis needle dramatically reduces false diagnoses and complications. The exact role of pericardiocentesis in trauma remains controversial. It may be lifesaving in the unstable patient before they are able to receive definitive surgical therapy.

Intracardiac Injection

Tiffany Abramson and Shoma Desai

INTRODUCTION

The practice of intracardiac injection originated in the 1800s and had been strongly advocated for years before it began to fall out of favor.¹⁻³ It was commonly performed throughout the 1960s, as it was thought to be the most expeditious route of drug delivery during

a cardiac arrest.^{4,5} By the mid-1970s, the practice of intracardiac injection declined. Safer and simpler routes of medication administration (i.e., intravenous, endotracheal, and intraosseous) became available. Experimental data suggested that there was no advantage to intracardiac injection over intravenous administration of medications.⁶ Cardiopulmonary resuscitation (CPR) must be interrupted to perform an intracardiac injection. The time required for this procedure may be prolonged in difficult patients or in inexperienced hands. Many serious complications may occur from an intracardiac injection.⁵ Intracardiac injection should be considered when no other access is readily available.⁷

ANATOMY AND PATHOPHYSIOLOGY

The technique of an intracardiac injection is similar to a pericardiocentesis (Chapter 48). Both techniques use the same anatomic landmarks and approach and involve the transthoracic insertion of a needle through the pericardium. The tip of the needle is inserted into the pericardial space when performing a pericardiocentesis. Intracardiac injection requires the tip of the needle to be inserted directly through the myocardium and into a cardiac chamber.

Echocardiography or bedside ultrasound may be useful in a pericardiocentesis to avoid the lung or myocardium.⁸ **However, time is of the essence when performing an intracardiac injection.** The objective is to quickly enter the myocardial cavity. Ultrasonographic guidance is generally not necessary. Certain comorbidities (e.g., chronic obstructive pulmonary disease [COPD], prior lung resection, or dextrocardia) may benefit from ultrasonographic guidance to avoid puncturing the lung.

The technique of intracardiac injection is rapid, simple to perform, and requires no special equipment. It begins with identification of the anatomic landmarks required to perform the procedure (**Figure 49-1**). For the subxiphoid approach, identify and palpate the xiphoid process of the sternum and the left costosternal angle. For the left parasternal approach, identify and palpate the left fourth or fifth intercostal spaces immediately adjacent to the sternum.

FIGURE 49-1. Intracardiac injection. The needle is inserted 1 cm to the left of the xiphoid process and aimed toward the left shoulder. The needle may also be inserted parasternally in the left fourth or fifth intercostal space (as denoted by the X).

INDICATIONS

Intracardiac injection should be considered when vascular access is not readily available in a patient in cardiac arrest. The goal of the procedure is to administer epinephrine rapidly to improve the likelihood of achieving a return of spontaneous circulation (ROSC).⁷ This is typically performed on patients in cardiac arrest with dysrhythmias such as asystole, pulseless electrical activity, or ventricular fibrillation.^{9,10} Epinephrine was equally effective when delivered via endotracheal tube, venous access, or intracardiac injection in one animal model study.⁶ The American Heart Association (AHA) recommendation and the advent of intraosseous lines have decreased the use of intracardiac injection during open cardiac massage.^{9,11} Intracardiac injection has slowly been phased out and should only be attempted if other routes of medication administration have failed.¹¹

CONTRAINDICATIONS

There are no absolute or relative contraindications in the moribund patient to performing this procedure. A few clinical conditions may make the procedure more technically difficult. COPD can shift the heart from its normal position and increase the risk of a pneumothorax. Anticoagulation may result in a hemopericardium and cardiac tamponade. Dextrocardia requires an alteration in needle positioning.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- 18 gauge spinal needle or 18 gauge 3½ inch long needle for adults
- 22 gauge spinal needle for children
- Syringes, 5 and 10 mL
- Nasogastric tube
- 1:10,000 epinephrine

Epinephrine is the only resuscitative medication that should be administered by intracardiac injection. Administer 1 mg of epinephrine as the initial and subsequent doses in an adult patient. Administer 0.01 mg/kg (or 0.1 mL/kg) of the 1:10,000 concentration of epinephrine in children.

PATIENT PREPARATION

This procedure is often performed on a patient who is clinically “dead” and as a last effort at resuscitation. An informed consent is not required to perform this procedure. The patient will be supine with CPR in progress. Insert a nasogastric tube to decompress the stomach if time permits. Apply povidone iodine or chlorhexidine solution to the area around the lower sternum, xiphoid process of the sternum, and upper epigastric and left costosternal angles. Identify by palpation the anatomic landmarks required to perform the procedure. Draw up the required dose of epinephrine into a syringe or use prefilled syringes. Attach a spinal needle to the syringe containing the epinephrine.

TECHNIQUES

The two routes for intracardiac injection are the subxiphoid and the left parasternal approaches (**Figure 49-1**). Both are used in a similar fashion. The left parasternal approach offers a more direct and shorter route. However, it is associated with a higher rate of complications. Both approaches require cessation of CPR to perform the procedure. It should take less than 10 seconds to perform this procedure and is within the allowable hands-off time frame of the 2015

AHA guidelines.^{7,9} **The procedure of intracardiac injection should be performed as rapidly as possible to avoid prolonged cessation of CPR, but not at the expense of safety to the Emergency Physician, Nurse, and/or ancillary staff.**

SUBXIPHOID APPROACH

The subxiphoid approach is preferred as it has a lower complication rate, including less risk of injuring the left anterior descending artery.¹⁰ Stop performing CPR. Stop ventilating the patient and allow the lungs to passively deflate. Identify the spot 1 cm to the left of the patient's xiphoid process in the costosternal angle (**Figure 49-1**). Insert the needle with the bevel up and at a 30° to 45° angle to the skin of the abdominal wall. Aim the needle toward the patient's left shoulder. Advance the needle while applying negative pressure to the syringe. Stop advancing the needle when blood flows freely into the syringe. This signifies that the tip of the needle is within the cardiac chamber. Quickly inject the epinephrine and withdraw the needle. Resume CPR and ventilation of the patient.

If the attempt at intracardiac injection is unsuccessful, withdraw the needle, flush it, and reattempt intracardiac injection. The needle can become plugged with subcutaneous fat. **CPR and ventilation must be resumed after each attempt at intracardiac injection whether successful or not.** Variations on the direction of the needle can be made for subsequent attempts. The needle may be directed toward the suprasternal notch, left mid-clavicle, or right mid-clavicle.

A spinal needle can be used as an alternative. This may be preferable due to the general population being overweight. Insert the spinal needle through the skin and into the subcutaneous tissue with its obturator in place. Remove the obturator when the tip of the spinal needle is in the subcutaneous tissue. Attach the syringe containing epinephrine to the spinal needle. Gently depress the plunger of the syringe to expel the air within the needle into the subcutaneous tissues. Advance the needle while applying negative pressure. Stop advancing the needle when blood flows freely into the syringe. Quickly inject the epinephrine and withdraw the needle. Resume CPR and ventilation of the patient.

LEFT PARASTERNAL APPROACH

This approach uses the fourth or fifth intercostal space, approximately 1 cm (or 1 finger breadth) lateral to the left sternal border (**Figure 49-1**). Stop performing CPR. Stop ventilating the patient and allow the lungs to passively deflate. Insert the needle perpendicular to the chest wall. Stabilize the needle with one hand and the syringe with the other. **Advance the needle with both hands and without excessive force.⁸ It is very easy to plunge into the heart if too much force is applied to the needle.** Apply negative pressure to the syringe as it is advanced. Stop advancing the needle when blood flows freely into the syringe. Quickly inject the epinephrine and then withdraw the needle. Resume CPR and ventilation of the patient.

If the attempt at intracardiac injection is unsuccessful, withdraw the needle, flush it, and reattempt intracardiac injection. The needle can become plugged with subcutaneous fat. **CPR and ventilation must be resumed after each attempt at intracardiac injection whether successful or not.** Variations on the direction of the needle can be made for subsequent attempts. The needle may be directed toward the suprasternal notch, left mid-clavicle, or right mid-clavicle.

PEDIATRIC CONSIDERATIONS

The technique of intracardiac injection for infants and children is essentially the same as that described for the adult patient.¹² While the subxiphoid approach has been adopted as the standard, the left

parasternal approach can also be effectively used. Use a 22-gauge spinal needle for infants and children. **Use caution when inserting and advancing the needle in pediatric patients since the skin and subcutaneous tissue are thin and easily penetrated.** The dose of epinephrine administered is weight-based.

COMPLICATIONS

Complications are rare in pooled data.^{5,13-15} A pneumothorax is the most common complication.¹⁶ This is especially true with the parasternal approach or in patients with COPD. Intramyocardial injection has been reported and is associated with intractable ventricular fibrillation.¹⁵ Rarer complications include hemopericardium and perforation of the stomach or liver. Other potential complications include coronary artery lacerations, myocardial lacerations, cardiac tamponade, and pulmonary artery lacerations.¹⁴ The use of a small-gauge spinal needle and the subxiphoid approach result in fewer complications as opposed to a large-gauge needle and the left parasternal approach.¹⁷ **Identification of the appropriate anatomic landmarks for needle insertion and careful adherence to proper technique can minimize complications.**^{12,15}

SUMMARY

Intracardiac injection is a possible route of medication delivery to a patient in cardiac arrest. Its popularity has declined in favor of safer and more effective methods of vascular access. Intracardiac injection should be considered as an alternative technique when intravenous access is not readily accessible and/or endotracheal medication administration has not provided the desired effect. It can be performed if it is done safely and does not encourage prolonged cessation of CPR during the procedure.

50

Needle Thoracostomy

Michael Gottlieb

INTRODUCTION

A tension pneumothorax is a unilateral progressive collection of air in the pleural space (**Figures 50-1 and 50-2**). If not treated, it results in increasing intrapleural pressures, shifting of intrathoracic structures, hypoxemia, and death. It occurs from a one-way air leak into the pleural cavity from the airway conduits, the lung, or the thoracic wall. The air leak causes air to enter the pleural cavity and become trapped, without a method of egress. Rapid decompression of the tension pneumothorax with a catheter-over-the-needle is known as a needle thoracostomy and is lifesaving.

A tension pneumothorax is an immediate life-threatening condition that requires prompt recognition and treatment to prevent the patient's imminent demise. The diagnosis may be suspected based on the patient's prior medical history, the mechanism of injury, physical examination findings, and a patient in extremis. **Importantly, treatment must not be delayed to obtain further diagnostic testing (e.g., chest radiograph).** These patients most often present with acute and dramatic cardiopulmonary compromise, which may be manifest by a combination of the following signs and symptoms: respiratory distress, chest pain, air hunger, hypotension, tachycardia, diaphoresis, unilateral absence of or decrease in breath sounds, hyperresonance to percussion, increased central venous pressure, hypoxemia, cyanosis, deviation of the cardiac point of maximal impulse, and tracheal deviation.

ANATOMY AND PATHOPHYSIOLOGY

The most common cause of a tension pneumothorax is mechanical ventilation with positive pressure in a patient with a visceral pleural injury.¹ A tension pneumothorax is present in 50% of

FIGURE 50-1. A right-sided tension pneumothorax. The traditional site for a needle thoracostomy is the second intercostal space in the midclavicular line.

FIGURE 50-2. Radiograph of a left-sided tension pneumothorax with no mediastinal shift. (Used with permission from reference 22.)

ventilator-associated pneumothoraces.² When this occurs in Intensive Care Unit (ICU) patients, they often have minimal functional reserve. To further cloud the issue, they are frequently on other supportive interventions (e.g., inotropic agents, complex ventilator settings), making their physical examination challenging and unreliable. They may also have a number of other coexisting factors that are making them unstable. This group of patients has a particularly disastrous course if a tension pneumothorax develops. Rapid diagnosis and treatment are imperative.³

The placement of a central venous catheter has been associated with the development of a pneumothorax. The incidence of this is approximately 3% to 6% with use of the subclavian approach, but this has been shown to decrease significantly with the use of ultrasound.⁴ A tension pneumothorax may be delayed in approximately 0.4% of attempts to gain central venous access. In one case report, a patient developed a tension pneumothorax while under general anesthesia 10 days after the placement of a subclavian central venous line.⁵

A tension pneumothorax may also occur in the setting of blunt or penetrating trauma of the lung. It may occur uncommonly following a tracheobronchial or esophageal injury. It may complicate a simple pneumothorax if the parenchymal lung leak does not seal spontaneously. In this case, the site of the lung injury acts as a one-way valve, allowing air entry into the pleural space and not allowing it to escape. Occasionally, chest wall defects may result in a tension pneumothorax in the case of a sucking chest wound, wherein the wound itself acts as a ball-valve mechanism. Refer to Chapter 53 for the details of an open chest wound. More rarely, it may occur following markedly displaced fractures of the thoracic spine.

In the past, based on studies using the canine model, the pathophysiology of this disease was considered to be associated primarily with a mechanical pressure-related phenomenon.⁶ Air accumulated in the involved pleural space and caused an increasing intrapleural pressure. This pressure caused compression of the ipsilateral lung, displacement of the diaphragm caudally, movement of the mediastinum and heart toward the uninjured side, kinking of the great vessels, and compression of the contralateral lung. This anatomic

shift of structures would result in impaired filling of the heart and a disastrous fall in cardiac output.⁷ Unfortunately, the canine model is not as similar to the human as was once thought. The mediastinum in the dog is more mobile. It is fenestrated, so that air communicates from one hemithorax to the other. Therefore elevations of intrapleural pressure in dogs would affect central structures and cause cardiovascular compromise more readily than in humans.

The intrathoracic pressure-related mechanism has come into question as the primary event. Experiments have been performed in goats, monkeys, sheep, and swine, all of which have a mediastinum that is more similar to that of the human than the dog.⁸⁻¹¹ These studies support the hypothesis that central hypoxemia is the primary factor in the lethality of a tension pneumothorax and occurs prior to the development of significant hypotension. In this hypothesis, the mechanical pressure-related phenomenon is a late event.

These mechanisms become more confusing and mixed in the ventilator-dependent patient. There is a lack of studies documenting hemodynamic changes in the human subject with a tension pneumothorax.¹²⁻¹⁵ In one case report, three ventilated ICU patients demonstrated decreased cardiac output as the first sign of a tension pneumothorax.¹³ The authors proposed that the absence of spontaneous breathing did not allow increased variations in negative intrathoracic pressure to act as a compensatory mechanism to prevent hemodynamic compromise. In another similar case, decreased cardiac output and mixed venous oxygen saturation were the dominant signs of a tension pneumothorax.¹⁴ Hemoglobin desaturation via pulse oximetry was shown to be the earliest sign in a ventilator-dependent patient with a tension pneumothorax.¹⁵

Electrocardiographic (ECG) changes may be seen in association with a tension pneumothorax. In a left-sided tension pneumothorax, the more commonly described ECG changes are a rightward shift of the mean frontal QRS axis, precordial T-wave inversions, reduced R-wave voltage, and decreased or alternating QRS amplitude.¹⁶⁻¹⁸ Other unique changes include PR-segment elevation in the inferior leads and reciprocal PR-segment depression in lead aV_R.¹⁹ One case report cited transient bradycardia, hypotension, and precordial ST-segment elevation, all of which reversed after treatment of a right-sided tension pneumothorax.²⁰

Numerous mechanisms have been proposed as the causes of these ECG changes. They include displacement of the heart, rotation of the heart around its anteroposterior or longitudinal axis, transient hypoxia, changes in coronary artery blood flow, changes in pleural pressure, pulmonary resistance, pericardial tension, acute ventricular dilatation, alterations in ventricular repolarization, pressure-induced atrial injury, and insulation of the chest wall from the associated air.¹⁶⁻²¹ The vast majority of ECG changes have been noted with left-sided rather than right-sided tension pneumothoraces. **The degree of pneumothorax and the severity of symptoms do not seem to correlate with the magnitude of the ECG abnormalities. In summary, ECG changes are not uncommon in tension pneumothorax and should not distract from the true diagnosis.**

In cases where the diagnosis is in doubt, consider using bedside ultrasound to assess for lung sliding.²² The transducer may require alternative placement in a tension pneumothorax (**Figure 50-3**). Lack of lung sliding, also referred to as the “barcode sign,” should suggest a pneumothorax and prompt needle decompression (**Figure 50-4**). There will be little to no respiratory variation seen upon visualization of the inferior vena cava (**Figure 50-5**). Refer to Chapter 8 for the details of the trauma ultrasound.

INDICATIONS

A tension pneumothorax must be considered in the differential diagnosis of any patient in extremis. If it is a possible etiology for the patient’s cardiopulmonary collapse, needle decompression

FIGURE 50-3. The use of ultrasound. **A.** Positioning of the probe. **B.** The location and axis of the right (RV) and left ventricle (LV) are altered secondary to increased left-sided pressure. (Used with permission from reference 22.)

should be performed without delay. In every circumstance, and especially in the emergent setting, one may not be able to be 100% certain of the diagnosis.²³⁻²⁵ However, needle decompression can be lifesaving. Consider a needle decompression in the correct clinical situation when the patient decompensates with any of the following: pulse oximetry less than 90% on high-flow oxygen, hypotension with no other etiologies, a respiratory rate over 35, a decreased level of consciousness, pneumothorax signs and symptoms, chest wall hyperexpansion and hypomobility, and an open chest wound.²³ A bedside ultrasound can be performed quickly while preparing for the needle decompression.^{26,27}

One setting that may be particularly confusing is in the dying patient with left precordial penetrating trauma. The immediate differential would be tension pneumothorax versus pericardial tamponade versus massive hemothorax. Physical examination findings are usually helpful but may also be confusing, mixed, or difficult to elicit in a chaotic and noisy resuscitation. **Needle decompression should be the first maneuver in this situation.** It may be lifesaving and will aid in the diagnosis. It is less invasive, quicker, and easier to perform than a pericardiocentesis or a thoracotomy. A tension pneumothorax is more common than pericardial tamponade in this setting. As for a massive hemothorax, a chest tube setup (Chapter 51) requires some time but should be requested at the time needle decompression is proceeding.

CONTRAINDICATIONS

There are no absolute contraindications to performing a needle thoracostomy to decompress a tension pneumothorax. In clinically stable patients, consider a bedside ultrasound to first assess for a pneumothorax.²⁶⁻²⁸ It is imperative to identify the anatomic landmarks properly and perform this procedure carefully if the patient has a known or suspected coagulopathy.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- 12 to 16 gauge catheter-over-the-needle, 4.5 cm in length
- Veress needle (optional)²⁹
- 5 or 10 mL syringe
- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Ultrasound machine (optional)
- High-frequency (10 to 15 MHz) ultrasound probe (optional)
- Sterile ultrasound probe cover (optional)
- Sterile ultrasound gel (optional)

PATIENT PREPARATION

Briefly describe the procedure to the patient if they are competent, able to understand, and cooperative. Place the patient supine. Some Emergency Physicians place the patient supine with the head of the bed elevated to 30°. This will allow the air to rise to the anterior upper chest. Unfortunately, this is not the most functional position. It is from the supine position that the patient can most easily be accessed and controlled by the greatest number of practitioners. The supine position is optimal to allow for other lifesaving maneuvers (e.g., airway management, cardiopulmonary resuscitation). Clean the skin of any dirt and debris in the area of the procedure. Apply povidone iodine or chlorhexidine to the skin.

Simultaneous with the performance of this procedure, other interventions should be requested including 100% face-mask oxygen (if the patient is not already intubated), pulse oximetry, cardiac monitoring, a chest tube setup, intravenous access, and stat chest radiography. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. Although this is an emergent procedure, aseptic technique should be followed when possible.

FIGURE 50-5. Sagittal ultrasound images of the inferior vena cava (IVC; arrow) during the respiratory cycle. (Used with permission from reference 22.)

TECHNIQUE

The safest, easiest, and most reliable site for a needle thoracostomy to decompress a tension pneumothorax is the second intercostal space in the midclavicular line (Figure 50-1).^{1,2,7,30} Attach a 12, 14, or 16 gauge catheter-over-the-needle onto a 5 or 10 mL syringe without the plunger. Identify the second intercostal space in the midclavicular line. Place the nondominant index finger over the needle insertion site. Grasp the syringe with the dominant hand. Insert the catheter-over-the-needle perpendicular to the skin and just above the superior border of the third rib (Figure 50-6A). This will avoid injury to the neurovascular bundle underlying the inferior border of the second rib. Some Emergency Physicians prefer to contact the upper portion of the third rib with the tip of the needle, walk it up the rib until it goes over the edge, and then advance it into the pleural space.

Advance the catheter-over-the-needle until a loss of resistance is felt as the tip of the needle penetrates the pleural space. A rush of air, with or without blood, will be heard escaping from the syringe. Stop advancing the catheter-over-the-needle. Advance the catheter until the hub is against the skin while simultaneously withdrawing the needle (Figure 50-6B).

ALTERNATIVE TECHNIQUES

Other sites have been described for performing a needle thoracostomy. These include the fourth or fifth intercostal space in the anterior or midaxillary line or the second intercostal space in the

anterior axillary line.³¹⁻⁴¹ There are several problems with these alternative sites. In the fourth or fifth intercostal space, the ribs are close together, with narrower interspaces making needle placement more difficult. There is more rib motion with breathing, and arm movement can make catheter dislodgment or kinking more likely. In the supine patient, air will rise ventrally rather than laterally. Practically speaking, during the resuscitation of the unstable patient, the most important position for the Emergency Physician is at the patient's head. Insertion of a catheter in the second intercostal space in the anterior axillary line is easier from this position than inserting a laterally placed catheter. The fourth or fifth intercostal space in the midaxillary line is the ideal space for a chest tube. Placement of the catheter in these alternative sites would mean having to penetrate more tissue, especially in the obese patient, making reaching the pleural space more difficult and dislodgment of the catheter more likely. The major drawback to using the fourth or fifth intercostal space is the risk of inadvertently inserting the catheter-over-the-needle below the diaphragm and into the liver on the right or the spleen on the left.⁴²

If the first attempt at needle thoracostomy fails to decompress the pleural space, a quick bedside ultrasound can be used to measure the chest wall thickness in order to determine the appropriate needle length and to confirm the presence or absence of a pneumothorax. Subcutaneous fat and tissue can be differentiated from air in the pleural space by the presence of the pleura seen deep to the pneumothorax and represented by a bright white line along with the absence of "lung sliding."

FIGURE 50-6. Decompression of a tension pneumothorax with a catheter-over-the-needle. **A.** The catheter-over-the-needle is inserted through the intercostal space and into the pleural cavity. **B.** The catheter is advanced and the needle is removed.

If the patient is in extremis, a chest tube should not be the primary therapy for a tension pneumothorax. The setup and performance of a formal tube thoracostomy takes much longer than rapid decompression with a catheter-over-the-needle. However, some experts recommend performing a finger thoracostomy in the fourth or fifth intercostal space (e.g., dissecting down to the rib and entering the pleura with a finger to release the air) followed by chest tube placement.⁴³ However, this is also more time consuming and should only be considered if needle thoracostomy is unsuccessful.

HANGING DROP TEST

A novel idea has been proposed to use the “hanging drop” test to identify the pleural space and determine if a tension pneumothorax is present.⁴⁴ It is quick, easy to perform, and uses supplies readily available in the Emergency Department. Be aware that gathering the supplies and performing this test can take a few minutes, thus delaying the needle decompression.

Using strict aseptic technique, insert a 4.5 cm long spinal needle into the second intercostal space and advance it until the tip is touching the upper border of the third rib. Remove the trocar. Place one to two drops of sterile saline or sterile water into the hub of the spinal needle. The fluid bubble will be elevated above the needle hub. Gently walk the needle up and over the edge of the third rib. Slowly advance the needle through the intercostal tissues while observing the fluid bubble. The negative intrathoracic pressure will suck the fluid bubble into the chest if there is no tension pneumothorax. The fluid bubble will be pushed out of the hub if a tension pneumothorax is present.

SPINAL NEEDLES

Some authors suggests using a spinal-type needle.⁴⁴ This cannot be recommended for two reasons. First, if a tension pneumothorax is present, the sharp needle should not be advanced or left in the pleural cavity to relieve a tension pneumothorax. It can puncture an organ or blood vessel. Second, the spinal needle would have to be removed and the procedure repeated with a catheter-over-the-needle to leave a catheter in place while preparing for and inserting a chest tube. Consider using a catheter-over-the-needle to perform this procedure to avoid these issues. If a longer catheter-over-the-needle is required, consider using the catheter-over-the-needle from a central line kit or a percutaneous cricothyroidotomy kit.^{45,46}

RUSSELL PNEUMOFIX

The Russell PneumoFix Decompression Needle (Bound Tree Medical, Dublin, OH) is designed for decompression of a tension pneumothorax, a simple pneumothorax, and a pleural effusion. It is a 12 gauge needle with an 11 cm long catheter with graduated markings (Figure 50-7). The catheter is quick and simple to insert without the need for a skin incision. The Veress-tipped needle minimizes injury to the lung. It has a low-pressure, one-way valve that allows air and fluid out. It is long enough to reach the pleural cavity in obese patients.

PEDIATRIC CONSIDERATIONS

The basic technique is the same in pediatric patients. Use a smaller length and gauge catheter-over-the-needle in pediatric patients. A 20 or 22 gauge, 1 inch or 2.5 cm catheter-over-the-needle should be used in preterm children and neonates. This same size can also be

FIGURE 50-7. The contents of the Russell PneumoFix kit. (Photo courtesy of Bound Tree Medical.)

used in children up to approximately 1 to 2 years of age. Between the approximate ages of 2 and 6 years, consider using an 18 or 20 gauge, 1.5 inch or 3.75 cm long catheter-over-the-needle. Over the age of 6 and into early adolescence, consider using a 16 or 18 gauge, 4.5 cm long catheter-over-the-needle. Use the adult size catheter-over-the-needle for older adolescents or obese children. **It is important to note that these are only recommendations based on average body sizes.** The individual child's size and body habitus need to be taken into consideration when choosing a catheter-over-the-needle size and length.

Some physicians prefer to use a butterfly needle with attached tubing instead of a catheter-over-the-needle in preterm children, neonates, and up to the first year of life.⁴⁷ Select a butterfly needle size as described above. Place sterile water or sterile saline in a sterile specimen cup. Insert the distal hub end of the butterfly tubing into the bottom of the specimen container and submerged in the liquid. Tape the tubing onto the rim of the specimen container to secure it and ensure it does not pull out of the liquid in the specimen container. Insert the butterfly needle into the pleural space as described above. Air bubbles will emerge from the tubing and into the sterile liquid as the tension pneumothorax is decompressed. The specimen container also forms a water seal, preventing flow of air into the pleural space, until a tube thoracostomy can be performed. Consider using a small gauge catheter-over-the-needle instead of a butterfly needle to avoid the problems described previously with using a spinal needle.

ASSESSMENT

Once the catheter has been placed into the pleural space, a gush of air should rush out of the syringe. **The procedure will have converted a tension pneumothorax into a simple pneumothorax requiring a tube thoracostomy.** The patient should improve both hemodynamically and symptomatically. Saturations on pulse oximetry should rise after the decompression. If this does not occur, too short of a catheter-over-the-needle may have been used and the procedure should be repeated with a longer one. If a longer catheter-over-the-needle is not available, rapidly perform a tube thoracostomy. Another possibility is that the pleural space was entered appropriately but the diagnosis was incorrect. In this event, alternative causes of the patient's shock state should be sought and consideration should be given to the placement of a “prophylactic” chest

tube. This may prevent later sequelae from the iatrogenic catheter stab wound to the chest and simplify further workup and monitoring of this unstable patient.

AFTERCARE

After insertion of the catheter and improvement in the patient's clinical status, the immediate life threat has been treated. Secure the catheter against the skin with a suture or an assistant holding it in place. **Continue to observe and monitor the patient closely for recurrence of the tension pneumothorax and procedural complications.** Establish intravenous access, cardiac monitoring, and pulse oximetry if not already done. Obtain baseline laboratory studies, an arterial blood gas, and a chest radiograph. Obtain a thorough history and physical examination to search for the etiology of the tension pneumothorax. **A definitive chest tube should be placed using sterile technique to prevent recurrence of the tension pneumothorax and to treat the simple pneumothorax.** Refer to Chapter 51 for the complete details regarding the placement of a chest tube. After a chest tube is inserted, remove the needle thoracostomy catheter and place a simple bandage over the puncture site.

COMPLICATIONS

An incorrect diagnosis of a tension pneumothorax in an unstable patient is always a possibility, even in the best of hands.^{48,49} If this is the case, the cause of the patient's shock state must still be aggressively sought and treated. A prophylactic chest tube should be considered for a presumed parenchymal lung injury and potential pneumothorax from the needle thoracostomy.⁵⁰⁻⁵² This is especially true if the patient is going to be transported out of the resuscitation area, will be given a general anesthetic, or is to be placed on positive-pressure ventilation.

Failure to reach and decompress the pleural space is the major argument against the use of needle thoracostomy. Depending on the patient's body habitus and the catheter length, the pleural space may not have been reached to be decompressed. In a study from the United Kingdom, the chest wall thickness was estimated to range from 1.3 to 5.2 cm by ultrasound in the second intercostal space.⁵³ A 3.0 cm cannula would fail to penetrate into the pleural cavity in 57% of the patients in this study. A 4.5 cm cannula would fail to penetrate into the pleural cavity in 4% of the patients. In this case, the procedure should be repeated with a longer catheter-over-the-needle.⁵⁴ If one is not immediately available, a tube thoracostomy should immediately be performed.

Several studies have evaluated chest wall thickness using ultrasound and computed tomography (CT) scans in order to determine the needle length required to appropriately decompress the pleural space in the general adult population. Initial studies using ultrasound seemed to indicate that using needle lengths of 4.5 cm would be sufficient to reach the pleural space in most patients.^{53,55} More recent studies using CT have shown that chest wall thickness varies significantly by gender and age.⁵⁵⁻⁵⁹ One study found that chest wall thickness was greater than 4.5 cm in 10% of men younger than age 40 and 19% of men older than age 40.⁵⁶ The same study found that almost one-third of women less than 40 years of age had a chest wall thickness greater than 4.5 cm, falling to one-fourth for women over 40. The mean chest wall thickness was found to be 5.36 cm in autopsy CT scan studies.⁵⁹ The authors recommended use of a 3.25 inch or 8 cm long catheter-over-the-needle. Others also recommend using longer needles.^{37,41,54,55,60} It is important to be aware of these variations. However, most authors still advocate using a needle length of 4.5 cm, because longer

needle lengths can increase the risk of vascular, pulmonary, or cardiac injury.^{61,62}

The second intercostal space in the midclavicular line is the traditional location for a needle thoracostomy. A prospective study of needle thoracostomy sites found that providers often place it more medial than recommended.^{63,64} Deviation from this insertion point is more likely to be associated with vascular injury and hemorrhage. This includes injury to the internal mammary artery medially, subclavian vessels superiorly, and the pulmonary trunk and heart inferiorly.

After the initial decompression of a tension pneumothorax, the catheter may become dislodged, clotted, or kinked. **If the tension pneumothorax recurs, immediately repeat the procedure.** Once needle decompression is reaccomplished, perform a tube thoracostomy. If possible, a tube thoracostomy can be initiated by the Emergency Physician while other members of the resuscitation team continue with other interventions. This would help prevent recurrence of the tension pneumothorax while other interventions (e.g., CPR, intubation, venous access) are being performed.

There may be additional complications secondary to the catheter placement.⁶¹⁻⁶⁷ A local hematoma or underlying lung laceration may occur. Infectious agents may be introduced into the pleural cavity. If the catheter-over-the-needle is introduced under the inferior border of the rib instead of over the superior border of the rib, the intercostal vessels or nerve may be lacerated. **Proper technique in placing the catheter-over-the-needle should be observed to minimize preventable complications.**

The traditional approach to relieving a tension pneumothorax is the placement of a large-bore needle in the ipsilateral second intercostal space. This may work in the "standard" patient where there are no adhesions or scarring in the pleural space. However, this may not be the proper needle location in the patient with prior pulmonary disease, pleural disease, or pleural adhesions. The classic hospital patient in this category is the patient with adult respiratory distress syndrome on positive end-expiratory pressure (PEEP) with high airway pressures who develops a loculated tension pneumothorax. The needle placed in the standard manner often fails to reach the affected pleural area. Stat chest radiographs are often required to help guide placement of the needles and/or chest tubes in these more complex patients.⁷ Bedside ultrasonography is also useful to help guide the procedure.

The needle thoracotomy procedure is not without its complications. This leads some to question the performance of a needle thoracostomy instead of just performing a tube thoracostomy.^{47,68} There are no clinical trials comparing needle versus tube thoracostomy to relieve a tension pneumothorax in human subjects. This study was recently undertaken in a swine model.⁶⁴ The authors demonstrated that a properly performed needle thoracostomy is as effective over a 4-hour period as a tube thoracostomy. While the authors did not record the time it took to perform the procedures, performing a needle thoracostomy is quicker, easier, and simpler and now just as effective when compared to a tube thoracostomy.

SUMMARY

A tension pneumothorax is a clinical diagnosis that is often made in an agonal patient with respiratory distress, absent or decreased breath sounds over a hemithorax, and severe cardiopulmonary compromise. Needle thoracostomy to decompress the tension pneumothorax should be performed immediately. The traditional site is the second intercostal space in the midclavicular line. The site of needle insertion seems to be changing. This lifesaving procedure is quick, simple to perform, and requires minimal equipment. A needle thoracostomy should be followed as soon as feasible by a tube thoracostomy.

Tube Thoracostomy

Kimberly T. Joseph and John C. Kubasiak

INTRODUCTION

A tube thoracostomy is the placement of a tube through the thoracic wall and into the pleural cavity. It is commonly referred to as a chest tube. It is placed to evacuate air, blood, or other fluid that collects within the pleural space. The etiology of the air or fluid collections can be due to iatrogenic complications, infection, lung disease, malignancy, or trauma.

Thoracic trauma accounts for nearly one-quarter of all trauma-related mortality.^{1,2} Some injuries require surgical intervention. Most injuries are treated nonoperatively. Injuries to the bronchi, chest wall, esophagus, lung, or trachea may lead to the presence of abnormal air and/or fluid in the pleural space. The use of a tube

thoracostomy (i.e., chest tube) in these situations may be diagnostic and therapeutic. Historically, closed-tube drainage of the pleura has been used for various indications for more than a century.³ This chapter deals primarily with the use of tube thoracostomy following trauma. Much of the information remains the same regardless of whether the patient is a trauma victim or a medical patient.

ANATOMY AND PATHOPHYSIOLOGY

The diaphragm and accessory muscles of respiration contract and generate negative pressure within the pleural space on inspiration. Penetration of the visceral or parietal pleura due to injury disrupts this pressure gradient and allows air to enter the “potential space” between the pleurae and results in a pneumothorax.^{1,2} **A simple pneumothorax is the accumulation of air that is not under pressure within the pleural space (Figure 51-1).**⁴ It may cause the ipsilateral lung to collapse. The increased pressure in the thoracic cavity may push the mediastinum toward the noninjured side as air continues to accumulate and if there are no adhesions. This can cause angulation of the atriocaval junction, impairment of atrial filling, and a subsequent decrease in cardiac output manifest by hypotension. **The presence of a pneumothorax under pressure accompanied by respiratory and/or circulatory compromise is a tension pneumothorax until proven otherwise and is an immediate life threat (Figure 51-2).**

There are two important points to remember about a tension pneumothorax. It is a clinical diagnosis based on the patient's presenting signs and symptoms. Do not wait for a chest film to establish the diagnosis. The initial treatment of this entity is needle decompression or finger decompression followed by tube thoracostomy. A large-bore needle is inserted in the second intercostal space (ICS) in the midclavicular line at the superior border of the rib. A gush of air will ensue if the patient has a tension pneumothorax and the symptoms will improve. This converts the tension pneumothorax to a simple pneumothorax requiring a chest tube for more definitive management. Refer to Chapter 50 for complete details regarding the needle thoracostomy procedure.

The frequent inadequacy of needle decompression using standard length needles has been noted as obesity rates increase. Recent literature has recommended using 8 cm long needles to assure

FIGURE 51-1. Chest radiographs. **A.** Left-sided pneumothorax and hemothorax. **B.** Right-sided pneumothorax. (Used with permission from reference 4.)

FIGURE 51-2. A tension pneumothorax.

adequate entry into the pleural space. Some authors advocate using the fourth ICS in the anterior axillary line.⁵ There is also support for “simple” or “finger” thoracostomy performed in the fourth ICS.^{6,7} Either technique is acceptable as long as the pleura is adequately decompressed.

An open pneumothorax is caused by a traumatic chest wall injury that results in a defect that is greater than or equal to two-thirds the diameter of the patient’s trachea (Chapter 53). Air passes via the path of least resistance (i.e., the defect) and leads to equilibration of the intrathoracic and extrathoracic pressures. This compromises oxygenation and ventilation. **An open pneumothorax is an immediate life threat.** Initial treatment may consist of a nearly occlusive “three-sided” dressing creating a one-way valve for egress of air from the pleural cavity. Alternatively, the patient may be placed on positive-pressure ventilation. The chest tube can then be inserted at a site remote from the actual defect.

Injury to the chest may result in laceration of vascular structures (e.g., great vessels, heart, intercostal vessels, internal mammary arteries, or lung parenchymal vessels). The body can absorb small amounts of free blood from the pleural space. The presence of free blood over a prolonged time leads to an increased risk of infection and fibrosis.^{3,8} The body cannot effectively clear large quantities of blood or clot from the pleural cavity. Blood in the pleural space (i.e., a hemothorax) can in most cases be treated with the insertion of a chest tube. A tube thoracostomy is usually followed by urgent surgical intervention when a major systemic or pulmonary vessel has been injured and results in a massive hemothorax (i.e., > 1500 mL of blood in the pleural space).

Penetrating wounds or blunt rupture of the thoracic esophagus may result in a hydrothorax, pneumomediastinum, pneumothorax, or some combination. Suspect esophageal injury in any patient with a knife or ice pick wound in a suspicious location, a transmediastinal bullet trajectory, or a severe and sudden compression of the chest or abdomen.² A tube thoracostomy is used as part of the treatment if a hydrothorax or pneumothorax is a presenting finding. These patients require urgent surgical attention. Tube thoracostomy may be used in the treatment of traumatic chylothorax resulting from an injury to the thoracic duct.

One special circumstance deserves mention. Certain patients who have sustained significant blunt trauma to the torso may have a

diaphragmatic rupture. **Chest radiographs may reveal an air density in the hemithorax that could be mistaken for a pneumothorax.** This may represent the presence of the stomach or colon in the thoracic cavity. Extra care must be taken when entering the pleural cavity so as not to injure a hollow viscus inadvertently when a chest tube is inserted in such a case.

INDICATIONS

The indications for a tube thoracostomy following blunt or penetrating trauma to the chest include the presence of a chylothorax, hemopneumothorax, hemothorax, hydrothorax, simple pneumothorax, or a tension pneumothorax (**Figures 51-1 and 51-2 and Table 51-1**). A chest tube may be placed prophylactically in patients with penetrating injuries to the chest who do not have evidence of a pneumothorax on initial chest radiographs but are expected to undergo endotracheal intubation and general anesthesia. The medical indications for a tube thoracostomy include an empyema, malignant pleural effusions, pneumothorax, pleurodesis, and recurrent pleural effusions. Perform a tube thoracostomy after the needle or finger decompression of a tension pneumothorax to convert it to a simple pneumothorax.

OCCULT PNEUMOTHORAX

Traumatic pneumothoraces and hemothoraces that are not evident on plain chest radiographs are being diagnosed more frequently with computed tomography (CT).⁹ The question then arises as to whether these pneumothoraces should be treated. The management of these “occult pneumothoraces and hemothoraces” is somewhat controversial. One study looked at 40 patients who sustained chest trauma and were discovered by CT scan to have pneumothoraces.¹⁰ The study concluded that patients undergoing positive-pressure ventilation should have placement of a chest tube. The study could not confirm that patients with small pneumothoraces who were not going to be ventilated could safely be observed. A review of 2326 CT scans, 80.5% after negative chest radiographs, noted 102 occult pneumothoraces and/or hemothoraces.¹¹ Only 12 of these patients required tube thoracostomy. Similar results were found for small, isolated occult hemothoraces.¹² A smaller study noted a higher percentage of patients requiring tube thoracostomy, but these patients were undergoing

positive-pressure ventilation.¹³ Nonprogressive occult pneumothoraces can usually be managed without a tube thoracostomy.¹⁴ Close clinical observation and/or follow-up plain radiographs are recommended. An initially occult pneumothorax that is increasing in size or is in a patient who develops respiratory distress requires a tube thoracostomy.¹⁴ A patient with an occult pneumothorax who requires endotracheal intubation, general anesthesia, and/or positive-pressure ventilation is an indication for a tube thoracostomy.¹⁵

CONTRAINDICATIONS

The only absolute contraindication to performing a tube thoracostomy is in the patient who requires an open thoracotomy. Although there are no firm contraindications to performing a tube thoracostomy in a trauma patient, there are some areas of controversy. There is increasing interest in conservative management of smaller traumatic pneumothoraces, particularly in blunt trauma.^{16,17} There is less support for conservative management in penetrating trauma.⁹ A South African study found that conservative management was safe in cases of small pneumothoraces in patients with stab wounds.¹⁸ There is currently no indication for conservative management of pneumothoraces caused by gunshot wounds. Repeat chest radiographs within 3 to 6 hours to rule out an enlarging pneumothorax or the delayed manifestation of a hemothorax if observation is selected for a patient with a traumatic pneumothorax.^{2,10}

Some physicians have begun managing small pneumothoraces with catheter aspiration rather than tube thoracostomy. Much of the evidentiary support for this comes from literature regarding spontaneous pneumothoraces.^{19,20} **Tube thoracostomy remains the safest and most complete method of evacuating pneumothoraces and hemothoraces due to traumatic injury.**^{21,22}

There are several relative contraindications to performing a tube thoracostomy in the medical patient. These include the presence of a skin infection over the chest tube insertion site, a coagulopathy, large pulmonary blebs or bullae, pulmonary adhesions, loculated pleural effusions, tuberculosis, or previous tube thoracostomies. These patients may require CT or ultrasound guidance to place the chest tube. Correct a coagulopathy before the chest tube is inserted if placement is not required emergently.

There has been some suggestion in the literature that there may be a role for the prehospital placement of chest tubes.^{21,23-25} Properly trained aeromedical crews and Physicians in some systems frequently perform tube thoracostomies in the field. This has not gained widespread acceptance.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- 10 to 20 mL syringe
- Local anesthetic solution with epinephrine (1% lidocaine or 0.25% bupivacaine)
- 25 or 27 gauge needle
- #10 scalpel blade on a handle
- Kelly clamps, large and medium
- Chest tubes, sizes 12 to 42 French
- Sterile water
- Chest tube drainage apparatus with a water seal
- Christmas tree connector
- Suction source and tubing
- Needle driver

- Mayo scissors, large curved
- Size 0 or 1-0 suture, silk or nylon
- Petrolatum-impregnated gauze
- 4 × 4 gauze squares
- Adhesive tape, 3 to 4 inches wide
- Sterile drapes
- Sterile gloves and gown
- Surgical cap
- Face mask with a face shield or goggles
- Tincture of benzoin spray or swabs
- 0.25% bupivacaine

Most hospitals and Emergency Departments have prepared their own “chest tube trays” that contain all the equipment required to place a chest tube except the chest tubes, local anesthetic solution, and a collection system. These last three items will vary based on the etiology of the air and/or fluid in the pleural cavity, the age and size of the patient, and physician preference. Commercially produced chest tube kits are also available.

Chest tubes used in the Emergency Department are hollow, clear, straight plastic tubes (**Figure 51-3**). The distal end of the chest tube has numerous fenestrations or holes that allow the passage of air and/or fluid into and through the tube. A radiopaque stripe allows for radiographic localization of the chest tube after it is inserted into the patient. The proximal end of the chest tube is beveled to allow it to fit better on a plastic connector.

Chest tubes are available in numerous sizes and from multiple manufacturers. The lower the number, the smaller is the size of the chest tube. A spontaneous pneumothorax may be drained with an 18 to 26 French tube in adults, a 14 to 16 French tube in children, a 12 to 16 French tube in infants and small children, and a 8 to 12 French tube in neonates. Traumatic pneumothoraces are usually drained with a 28 to 32 French tube in adults and a 16 to 20 French tube in children. Traumatic hemothoraces, traumatic hemopneumothoraces, and empyemas require larger size tubes. A 36 to 42 French tube in adults and a 20 to 24 French tube in children will provide adequate drainage without becoming occluded by blood clots or purulent material.

The procedure requires the use of a large Kelly clamp to bluntly dissect a subcutaneous tract, to puncture the tract, and to dilate a tract through the intercostal muscles. The Kelly clamp requires the

FIGURE 51-3. The chest tube. The proximal end is beveled, while the distal end is fenestrated.

FIGURE 51-4. The Centurion Blunt Dissector. (Photo courtesy of Centurion Medical Products, Howell, MI.)

Emergency Physician to pull the ringed handles apart and in opposite directions to open the jaws of the clamp. Opening the jaws of the Kelly clamp when it is within the subcutaneous tissues or intercostal muscles can be quite difficult. The Centurion Blunt Dissector clamp (**Figure 51-4**) was specifically designed to aid in the insertion of a chest tube (Centurion Medical Products, Howell, MI). The mechanical action of this clamp is opposite that of the Kelly clamp. The jaws are closed in the resting position and the ringed handles are held open with a spring mechanism. The ringed handles are squeezed together to open the jaws of the clamp. Some physicians find this is a more natural, intuitive, and easier motion to perform. This chest tube clamp is disposable and available individually or incorporated into a chest tube insertion tray.

DRAINAGE SYSTEMS

It is important to know how to use the drainage system available at your institution to prevent any complications arising from the use of these devices. The classic glass bottle system with rubber corks is rarely, if ever, used in the United States today in the Emergency Department. Commercially available drainage systems are currently available in most hospitals (**Figure 51-5**). They are made of lightweight plastic, sterile, and intended for single-patient use. They are preassembled, disposable, and may be used for autotransfusions (Chapter 228). They have clear plastic covers to allow easy visualization of the fluid within the unit.

The system is a single unit that consists of three or four chambers, depending on the manufacturer. The first chamber connects to the chest tube with flexible rubber tubing. It collects blood, clots, and/or other fluid expressed through the chest tube. The second chamber is the water seal. It allows one-way flow of air away from the patient and maintains a negative intrathoracic pressure gradient compared to the atmosphere. The third chamber is the suction regulator, which attaches to the wall suction. It draws in atmospheric air when needed to limit the negative pressure of the vacuum. Some manufacturers have included a fourth chamber to assess the patient's intrapleural pressure.

PATIENT PREPARATION

Explain the risks, benefits, complications, and aftercare to the patient and/or their representative if time and the patient's clinical condition permits. Obtain an informed consent for a tube thoracostomy or document in the medical record the verbal discussion whenever possible. A tube thoracostomy is often performed under urgent or emergent conditions following trauma. Lifesaving care should always proceed on the patient's behalf with the appropriate documentation in the medical record after the patient is resuscitated.

There has been considerable discussion in the literature regarding the use of antibiotics in patients requiring a tube thoracostomy for trauma in the hope of preventing an empyema.²⁶⁻²⁸ The Eastern Association for the Surgery of Trauma (EAST) practice management guidelines work group reviewed the literature regarding the use of antibiotics in conjunction with chest tube insertion.²⁹ They found several trials that evaluated infectious complications after a tube thoracotomy using Centers for Disease Control and Prevention (CDC) criteria. The studies each had their weaknesses. The working group recommended that there was sufficient class I and class II evidence to support a recommendation of administering a first-generation cephalosporin intravenously just before making the skin incision and continuing the intravenous antibiotic for 24 hours.²⁹

The administration of parenteral analgesics, sedatives, and/or procedural sedation (Chapter 159), if not contraindicated, will be greatly appreciated by the patient as the procedure is quite painful. Employ the appropriate protocols for patient monitoring. Place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them during and after the procedure. Frequently check vital signs.

Place the patient supine or semierect with the arm on the involved side raised away from the chest (**Figure 51-6**). Identify the fifth ICS in the midaxillary to anterior axillary line (**Figure 51-6**).^{30,31} Consider marking this point on the patient's skin with a pen or marking pen. Consider placing a soft restraint around the wrist to prevent the arm from moving during the procedure (**Figure 51-6**).

FIGURE 51-6. Patient positioning for a tube thoracostomy. Note the application of supplemental oxygen, pulse oximetry, cardiac monitoring leads, and a soft restraint.

Apply povidone iodine or chlorhexidine solution to the chest wall and allow it to dry. Apply sterile drapes to demarcate a sterile field. **Sterile technique should be observed and followed by all involved personnel. They should don a cap, mask, eye shield, sterile gown, and sterile gloves.**

Reidentify the fifth ICS in the midaxillary to anterior axillary line (Figure 51-6). This is the preferred site for chest tube insertion.³⁰ The reasons for this are twofold. The diaphragm rises during respiration to the level of the nipple. Chest tube insertion below the fifth ICS unnecessarily risks puncture of the diaphragm or abdominal organs. The area of the midaxillary line is the least muscular area of the chest wall and is thus an easier area from which to gain access to the pleural cavity.¹⁻³ This area is also described as the “safety space.” Its boundaries are the base of the axilla superiorly, the fifth ICS inferiorly, the lateral edge of the pectoris major muscle (i.e., anterior axillary line), and the lateral edge of the latissimus dorsi muscle (i.e., posterior axillary line).

Infiltrate local anesthetic solution into the chest wall and pleural cavity if the patient is awake and aware of their surroundings. This should be performed regardless of whether the patient receives parenteral analgesics, sedatives, and/or procedural sedation. Approximately 10 to 20 mL of local anesthetic solution with epinephrine (e.g., lidocaine or bupivacaine) is required to provide adequate analgesia. Consider using bupivacaine as it provides longer analgesia than lidocaine. **Be aware of the maximum weight-based volume of local anesthetic solution to administer to prevent toxicity (Chapter 153).** Raise a subcutaneous wheal of local anesthetic solution one interspace below the one to be used to insert the chest tube (i.e., the sixth ICS). Infiltrate local anesthetic solution subcutaneously and upward to a point above the fifth ICS. **Ensure the needle goes just above the upper border of the rib to avoid the neurovascular bundle under the bottom edge of the rib above (Figure 51-7).** Redirect the needle to anesthetize the intercostal muscles and parietal pleura of the fifth ICS. Advance the needle into the pleural cavity and inject 2 to 3 mL of local anesthetic solution to adequately anesthetize the pleura (Figure 51-7).

TECHNIQUE

The technique described here is an “open” technique as opposed to that employing the use of a trocar. Trocar-aided insertion of chest tubes is associated with a higher incidence of major complications and does not result in any significant saving of time.¹⁻³ **Never use a trocar for chest tube insertion.**

FIGURE 51-7. Infiltration of local anesthetic solution into the chest wall and pleural cavity.

Make a 3 to 5 cm incision with the #10 scalpel blade over the rib one ICS below the desired ICS (i.e., the sixth ICS) (**Figures 51-8 and 51-9 A**). Bluntly dissect a tract or tunnel with the 6 inch Kelly clamp in the subcutaneous tissue in a cephalic direction to the rib above (**Figure 51-9B**). Orient the clamp with the tips curved toward the skin. Advance the closed tips of the clamp in 1 cm increments and open the jaws to dissect the tract (**Figure 51-9B**). The tract should terminate at the upper border of the fifth rib. **This will avoid injury to the neurovascular bundle lying under the inferior border of the fourth rib.** Rotate the clamp 180° such that the tip is aimed just above the superior border of the fifth rib and toward the pleural cavity (**Figure 51-9C**). Briskly push the closed tips of the clamp through the intercostal muscles and parietal pleura and into the pleural cavity (**Figure 51-9C**). **This maneuver requires a significant amount of force to enter the pleural cavity.** A twisting motion as the clamp is advanced may facilitate penetration into the pleural cavity. The intercostal muscles will stretch and entering the pleural cavity will be difficult if the clamp is advanced slowly.

A loss of resistance associated with a rush of air or fluid occurs as the pleural cavity is entered with the closed tips of the clamp (**Figure 51-9C**). The fluid contained within the pleural cavity may exit the tract forcibly if under pressure. **It is important not to plunge too deeply with the clamp as the pleural cavity is entered.** The tips of the clamp can injure the diaphragm, great vessels, heart, or lung. The forward motion of the clamp can be partially opposed by bracing the nondominant hand on the underside of the clamp and applying counterpressure away from the patient as the clamp enters the pleural cavity.

Spread the jaws of the clamp to enlarge the tract through the subcutaneous tissue, intercostal muscles, and parietal pleura. Insert a finger through the tract and into the pleural cavity (**Figure 51-9D**). Feel the lung as it expands with inspiration and contracts with

FIGURE 51-8. The initial skin incision is made over the rib one interspace below the desired chest tube insertion site.

FIGURE 51-9. The tube thoracostomy. **A.** The skin incision is made. **B.** A tract is bluntly dissected in the subcutaneous tissues. **C.** The Kelly clamp is forced into the pleural cavity. **D.** A finger is inserted through the tract to feel for adhesions. **E.** The chest tube is held in the Kelly clamp and inserted through the tract. **F.** The chest tube is guided into the pleural cavity.

expiration. Rotate the finger to ascertain the presence or absence of adhesions (**Figure 51-9D**). **Gently break any loose adhesions between the lung and thoracic cage with the finger. Dense adhesions require the chest tube to be inserted at another site.**

Prepare to insert the chest tube. Estimate the distance from the skin incision to the apex of the lung by laying the chest tube over the patient. Apply a clamp onto the chest tube at the estimated site at which it should exit the skin incision. This location should be 4 to 5 cm proximal to the fenestrations in the chest tube. Cut off the beveled proximal end of the chest tube just above the bevel.

Grasp and clamp the tips of the large Kelly clamp onto the distal end of the chest tube. Insert the tips of the clamp and chest tube through the tract and into the pleural cavity (**Figures 51-9E and F**).³² Use the clamp to direct the tip of the chest tube posteriorly and superiorly. Alternatively, the dominant index finger can be placed through the tract to direct the chest tube. **The use of the finger in the tract is the preferred method to guide the chest tube.** The

finger will be able to confirm the proper intrapleural placement of the chest tube. Release the Kelly clamp and advance the chest tube until all the fenestrations are within the pleural cavity and the pre-placed clamp on the chest tube is at the skin incision. Hold the chest tube securely in place. Remove the Kelly clamp from the incision. Release the clamp on the chest tube.

Secure the chest tube with 0 or 1-0 silk or monofilament nylon suture (**Figure 51-10**). The many techniques that have been described for securing chest tubes are idiosyncratic and probably equivalent. Suffice it to say that the tube should be sewn in such a way that the incision is closed tightly around the tube to assure a better seal and that routine movements of the patient should not dislodge it (**Figure 51-10A**).³³

Place the first stitch as a simple interrupted stitch at one end of the skin incision (**Figure 51-10B**). Leave both ends of the suture long after tying the knot in the first stitch. Wrap the needle end of the suture firmly around the chest tube three or four times. Tie a knot in

FIGURE 51-10. Securing the chest tube to the thoracic wall. **A.** Proper knot tightness and wound approximation. The *long arrows* point to knots that are tied on the chest tube. The *short arrows* are the sealed skin incision and the area around the chest tube. (Used with permission from reference 33.) **B.** The stay suture. **C.** The purse-string suture.

FIGURE 51-11. Securing the chest tube. **A.** The chest tube has been secured with suture to the chest wall. **B.** An occlusive dressing has been placed over the incision and taped to the chest wall.

the suture to secure the chest tube to the skin (**Figure 51-10B**). Place the second stitch as a purse-string suture encompassing the chest tube (**Figure 51-10C**). Leave both ends of the suture long. Wrap both ends of the suture around the chest tube and tie a bow, not a knot. This stitch will be used later to close the skin incision after the chest tube is removed. Place simple interrupted or horizontal mattress sutures to close the remainder of the skin incision.

Apply an occlusive dressing over the incision site (**Figure 51-11**). Apply petrolatum gauze over the incision site and around the chest tube as it exits the incision. It seals the chest wall incision from the atmosphere and prevents air from the atmosphere from entering the pleural space from around the chest tube. Place gauze squares over the incision site and petrolatum gauze. Apply tincture of benzoin to the chest wall surrounding the gauze squares. Tape the gauze and chest tube to the torso. The ends of the tape should be adherent to the tincture of benzoin. **Do not place tape over the patient's nipple. Protect the nipple with a piece of gauze if the tape must cover the nipple.**

An alternative to the above dressing is the Centurion Chest Tube Anchor (Centurion Medical Products, Howell, MI). This is a sterile, adherent patch that surrounds the chest tube as it exits the skin (**Figure 51-12**). It forms an occlusive dressing. It has an attached cable tie to wrap around the chest tube and secure it in place. This cable tie replaces suturing the chest tube in place. The device can be trimmed to a smaller size for pediatric patients. The cable tie will secure all sizes of chest tubes.

Connect the chest tube to a drainage system (**Figure 51-13**), which is a self-contained multichamber device.³ The first chamber is a collecting chamber that connects directly to the chest tube. The second chamber contains a small amount of saline or water and acts as a one-way valve. This assures flow only in the direction away from the patient. The third chamber controls suction, with a capability of at least 20 cmH₂O suction, and attaches to the wall suction system. Commercially available systems encompass all three chambers in one unit (**Figure 51-5**).

ALTERNATIVE TECHNIQUES

CHEST TUBE LOCATION

Evidence is lacking and the recommendations vary regarding the location of a chest tube.³⁴ The chest tube tip can be directed toward the pleural cavity apex or base.³⁵ Direct the chest tube apically with

its tip above the aortic notch for a pneumothorax (**Figure 51-14**, area 1). Direct the chest tube basally with its tip just above the diaphragm for a hemothorax or a hemopneumothorax (**Figure 51-14**, area 2). Aiming superiorly decreases the likelihood of chest tube placement in the lung fissure.

PLEURAFLOW

The PleuraFlow Active Tube Clearance (PleuraFlow ATC; ClearFlow Inc., Anaheim, CA) was designed to be used in cardiac surgery. It has been adopted by some for use in trauma patients in the Emergency Department. The device uses a looped guidewire inside the chest tube (**Figure 51-15**). It is available for chest tubes that are pediatric and adult sizes. A magnetic slider on the outside moves the looped guidewire to clear any clots. It is simple to use and does not break sterility. The proximal end attaches to any drainage system. The guidewire can be removed if the chest tube

FIGURE 51-13. The chest tube is connected to a drainage system.

FIGURE 51-14. The chest tube can be inserted into the pleural apex (area 1) or pleural base (area 2). (Used with permission from reference 35.)

remains without the risk of clotting (i.e., resolution of the hemothorax with persistent pneumothorax).

SELDINGER TECHNIQUE FOR SMALL CATHETERS

Drainage of a hemothorax or pneumothorax can be accomplished using a small-bore pigtail or straight catheter in pediatric patients and adults (**Figure 52-19**).^{22,36-39} A straight catheter is preferred over a pigtail for traumatic hemothoraces due to the increased failure on insertion and complications.⁴⁰ An alternative is to use a central venous catheter if a pigtail catheter is not available.⁴¹ Attach a 16 gauge, 2 inch catheter-over-the-needle to a 5 or 10 mL syringe. Insert the catheter, as described above, aimed superiorly. **Insert the catheter-over-the-needle over the superior border of the rib to avoid the neurovascular bundle located on the inferior border of the rib.**⁴² Securely hold the needle and syringe so it does not move. Advance the catheter to the hub. Remove the needle and syringe. **Quickly cover the catheter hub with a gloved finger.** Insert the guidewire through the catheter (**Figure 52-19A**). **Hold the guidewire securely to prevent it from falling completely into the pleural cavity.** Remove the catheter over the guidewire and leave the guidewire in place (**Figure 52-19B**). Extend the skin incision with a #11 scalpel blade by 3 to 5 mm to allow the catheter into the pleural space without “crumpling” (**Figure 52-19C**). Advance the dilator over the guidewire and into the pleural cavity to dilate the tract (**Figures 52-19C and D**). A gentle twisting motion of the dilator as it is advanced will aid in its insertion into the pleural cavity (**Figure 52-19D**). Hold the guidewire securely. Remove the dilator while leaving the guidewire in place. Insert the catheter over the

A

B

guidewire and into the pleural cavity (**Figure 52-19E**). Remove the guidewire catheter. Attach the catheter to a drainage system and secure it as described previously.

DRAINAGE SYSTEMS

Drainage systems for a pneumothorax vary in style but function with the same “one-way valve” principle. The simplest method is a flutter valve. It is best illustrated by the following noncommercial method. Cut a premoistened finger from a sterile glove. Tie the proximal end to the thoracentesis catheter with a silk suture and cut the distal end so that it is open to the air (**Figure 52-20**).⁴³ This creates a flutter valve and allows air to escape with coughing or expiration and prevents air from reentering the pleural space on inspiration.

Commercial kits are available that can be used for outpatient management of a pneumothorax in some patients. The kit often contains a Heimlich flutter valve (**Figure 52-21**).^{43,44} **The arrow on the clear protective tube covering the Heimlich valve must point away from the patient.**⁴⁵ Suction is usually not needed. Outpatient management may be considered in stable patients with a primary spontaneous pneumothorax that is small, apical with initial lung reexpansion, and good apposition of the lung with the lateral chest wall.^{46,47} **The patient must be able to understand and comply with outpatient instructions, must have access to immediate help, and must return to an Emergency Department if symptoms arise.** Additional requirements include good residual lung function, normal oxygen saturation, and an air leak adequately treated by thoracentesis.⁴⁸ **A contraindication to using the flutter valve is a hemothorax.** A closed underwater seal system is recommended in these cases.

The Pneumostat (Maquet Getinge Group, Hudson, NH) is a single-use device (**Figure 52-22**). It attaches to a garment. The Pneumostat has multiple chest tube connectors. The air leak well provides quick and simple air leak confirmation. It has a 30 mL collection chamber and a needleless sampling port. It helps the patient ambulate sooner due to it being small and not cumbersome. It has a one-way valve for patient protection.

The TRU-CLOSE Thora-Vent (UreSil LLC, Skokie, IL) is an alternative device to the pigtail catheter and Heimlich valve combination (**Figure 52-23**). It is a one-piece unit that combines an intrapleural catheter and external one-way antireflux valve that attaches to the chest wall by an adhesive pad. Its insertion is quicker, easier, and simpler than a traditional catheter. It is inserted using a trocar. The diaphragm is used to indicate pleural entry and pneumothorax resolution. The low profile makes ambulation and outpatient management easier for the patient. This device is rarely available in the Emergency Department.

ULTRASOUND-GUIDED TECHNIQUE

The same sterile preparation applies to the ultrasound evaluation. A pneumothorax may be more readily identified with the patient positioned supine rather than upright with ultrasound. A 3.5 to 5.0 MHz phased-array transducer or 7.5 to 10 MHz high-frequency linear transducer is recommended.⁴⁹ The orientation of the transducer follows the convention that the marker should correlate to the reference point in the left upper corner of the monitor screen. Ultrasound can identify the safe location for the insertion of a chest tube.³⁰

The key US features of a pneumothorax include the absence of inspiration-expiration-related “lung slide,” loss of “comet tail” artifact, and broadening of the pleural line to a thick band (**Figure 52-17**).^{50,51} Compare the hemithorax suspected of having a pneumothorax to the unaffected side to confirm these findings in the case of a unilateral pneumothorax (**Figure 52-17**). Aspirate a pneumothorax using the ultrasound similar to a pleural effusion (Chapter 52) or insert a chest tube.⁵²

KATGUIDE

The KatGuide was developed for the safe and accurate insertion of a chest tube (Pleuratech, Denmark).³⁵ The device has a curved shape to place the chest tube (**Figure 51-16**). It consists of a handle,

A

B

C

FIGURE 51-16. The KatGuide. **A.** The device. **B.** The chest tube loaded. **C.** The device to insert the chest tube in the apex or the base. (Photos used with permission from reference 35.)

a middle part to load the chest tube, and a distal part that guides the chest tube. The KatGuide method is a blunt technique (i.e., dissection with a Kelly clamp, digital exploration, insertion of the distal end of the KatGuide pointing to the part of the pleural cavity that needs drainage followed by chest tube insertion). The chest tube is guided into the pleural cavity through the KatGuide instead of using a finger and Kelly clamp. The KatGuide enhances the chance of optimal chest tube positioning and reduces the risk of chest tube misplacement. The rounded tip and the insertion direction parallel to the lung surface prevent lung damage.

ASSESSMENT

Obtain an anteroposterior portable chest radiograph.⁵³ Observe the position of the chest tube. Remove the chest tube and insert a new one if it is bent, kinked, or in the fissure of the lung. If its tip is against the mediastinum, unsecure the tube, withdraw it a few centimeters, resecure the tube, and obtain a repeat radiograph. Remove the chest tube and insert a new one if it is in the subcutaneous tissue. Observe the fenestrations on the distal end of the chest tube in the radiograph. **They all must be within the thoracic cavity.** If not, remove the chest tube and insert a new one. **Never advance a chest tube further into the thoracic cavity after obtaining a chest radiograph to prevent tracking infectious material into the pleural cavity.**

Persistent bubbling in the system or failure of the lung to reexpand indicates a leak in the system.^{54,55} Check the system to ensure that all connections are secure. Place tape over the connections to eliminate leaks and prevent the components from becoming dislodged. Check the tubing for any holes or fissures. Examine the chest tube and the radiograph to confirm that all fenestrations are within the thoracic cavity. Replace the chest tube if all fenestrations are not within the pleural cavity. **An injury to the trachea, mainstem bronchus, a large bronchiole, or the esophagus can cause a persistent air leak.**^{54,55} A second chest tube can be inserted to keep up with the leak and prepare the patient for bronchoscopy and/or esophagoscopy to diagnose the etiology of the persistent air leak. Large or persistent air leaks usually represent proximal tracheobronchial injuries and may require urgent surgical intervention. Any persistent air leak should prompt a surgical consult.

AFTERCARE

Patients with chest tubes require close monitoring. If administered, continue prophylactic antibiotics for 24 hours. Obtain daily serial chest radiographs to monitor for resolution of the inciting process. The presence of air leaks from the chest tube indicates that the injury has not completely healed and the seal between the parietal and visceral pleurae has not yet been restored. Maintain suction until there is no evidence of an air leak. The acceptable minimal daily output from a chest tube as a criterion for removal varies according to the institution, the physician, and the reason for insertion. It is also unclear whether a trial period of water seal following suction is strictly necessary. There is literature to suggest that suction and water seal protocols for removing chest tubes are effective and have similar incidences of recurrent pneumothoraces.⁵⁶ There is literature supporting an abbreviated trial of water seal following suction as it may allow time for occult pneumothoraces to manifest themselves and alleviate the need for reinsertion of a chest tube.⁵⁷ Monitor the chest tube insertion site for signs of infection.

Check the chest tube and collection tubing periodically for blockage. The tubing may be milked or stripped to alleviate the blockage and avoid the need to replace the chest tube. **Milking refers**

to forcing air, fluid, or clots back into the chest. Stripping refers to creating negative pressure within the tubing to move fluid or clots distally and into the collecting chamber. To milk the tube, clamp or pinch the tubing shut distally while using the other hand to compress the tubing and move proximally to force the contents back into the thoracic cavity. To strip the tube, clamp or pinch the tubing shut proximally while using the other hand to compress the tubing and move distally followed by the sudden release of the proximal tubing.

CHEST TUBE REMOVAL

Be prepared to replace the chest tube if planning to remove a chest tube. Have all the necessary equipment and supplies readily available in case the patient urgently requires a new chest tube. Don gloves, a gown, a face mask with an eye shield or goggles, and a cap to prevent becoming contaminated when the chest tube is removed.

Place the patient supine or semirecumbent. The use of parenteral sedation and soft restraints is rarely necessary when removing a chest tube. Carefully remove the tape securing the chest tube to the chest wall. Be cautious when removing the tape if it covers the patient's nipple to prevent any injury. Remove the gauze squares and petrolatum gauze covering the incision site. Untie the bow securing the free ends of the purse-string suture that was previously placed. Cut the suture that is holding the chest tube to the chest wall. Remove this suture. Place the first half of a surgeon's knot in the free ends of the purse-string suture. Pass the ends of the suture to an assistant. **Instruct the patient to inhale or exhale fully and hold their breath.**⁵⁸ **This results in a Valsalva-type maneuver and will prevent ambient air from being drawn through the chest wall and into the pleural cavity.** Quickly and smoothly remove the chest tube while the assistant cinches down the knot of the suture to seal the skin incision. Tie additional knots to secure the purse-string suture. Place petrolatum jelly or topical antibiotic ointment over the incision. Cover the site with gauze squares and tape it securely.

Sometimes a purse-string suture is not used in the insertion of a chest tube. Ensure that the chest tube site is completely occluded by the assistant. This is ideally performed with petrolatum and standard gauze as the chest tube is being removed.

Observe the patient for 4 to 6 hours for any signs of cardiovascular or respiratory compromise. Obtain expiratory posteroanterior and lateral chest radiographs if the patient remains asymptomatic. Evaluate the radiograph for the presence or recurrence of a hemothorax, hydrothorax, pneumothorax, or pyothorax.^{59,60} The dressing may be removed in 24 to 48 hours. Remove the chest wall incision sutures in 8 to 10 days.

COMPLICATIONS

Tube thoracostomy is often described as a simple procedure. However, a chest tube can result in serious complications (e.g., injuries to thoracic and abdominal organs) if it is not performed with care and attention.^{1,2,61-68} An unusual occurrence of sudden death following chest tube insertion has been reported.⁶⁹ It was attributed to hemorrhage near the vagus nerve causing irritation and stimulation of the vagus nerve and refractory bradycardia. Injury to the thoracic duct from the chest tube being inserted too deeply can result in a chylothorax.⁷⁰ Injury to the heart and great vessels can occur if the chest tube is placed anteriorly or a trocar was used to insert the chest tube.⁶⁴ Lung injury can occur if the clamp plunges inward on entering the pleural cavity. **It is imperative that the Kelly clamp be controlled as it enters the pleural cavity.** If the lung is adherent to the chest wall, it may be penetrated by the Kelly clamp or the chest tube. **A trocar should never be used to insert a chest tube as it can**

cause significant injury to the heart, lung, or other intrathoracic structures.^{64,67}

Other complications associated with chest tube placement and removal include recurrent, residual, and loculated pneumothoraces.⁶² These may require the placement of additional chest tubes. Placement of the chest tube too high can result in a Horner's syndrome or subclavian artery occlusion.^{71,72} Insertion too far from the left side can result in injury of the right side.⁷³ The wrong ICS can be identified and the chest tube inserted too high or low.³¹ The lung can herniate through the incision site.⁶⁴ The chest tube can compress and injure the long thoracic, phrenic, and ulnar nerves.^{64,74,75} A retained hemothorax may require decortication and may develop into an empyema.^{8,76,77} The lung may not expand due to the bronchus being plugged (e.g., mucus). Allergic reactions can occur to the skin preparation, local anesthetic solution, or tape.

Posttraumatic empyema remains a serious complication of thoracic trauma with incidences ranging from 2% to 25%.^{1,2,8,77} The etiology of the infection is not always clear. A break in sterile technique on chest tube insertion, nosocomial pneumonia, superinfected pulmonary contusion, and undrained hemothoraces have all been implicated. **Empyemas attributed to the chest tube insertion are completely preventable complications that can be avoided by strict adherence to aseptic technique.** Other infectious complications include chest wall cellulitis and necrotizing fasciitis.^{64,78}

Bleeding can occur from several sites. Incision site bleeding is often due to superficial venules and arterioles. The application of pressure and suturing the incision closed will alleviate this bleeding in most cases. An intercostal artery or vein can be lacerated if the dissection or penetration into the pleural cavity occurs along the inferior surface of a rib. Securing the chest tube against the inferior surface of the rib may tamponade the bleeding. Attempt to tamponade the bleeding with a Foley catheter if it continues. Insert the catheter into the pleural cavity, inflate the cuff, and withdraw the catheter to lodge the inflated cuff against the posterior surface of the rib. Another option is to extend the incision to expose and ligate the bleeding vessel. Lung injury and bleeding from penetration into the pleural cavity are often self-limited and minor. Rarely will an injury be serious enough to warrant surgical intervention. **A trocar should never be used as risk of injury to intrathoracic structures is significantly increased.** An anteriorly placed chest tube should be at least 3 cm from the lateral border of the sternum to prevent injury to the internal mammary artery.

The chest tube can become occluded and stop functioning. A large tube should always be inserted if its purpose is to drain blood, clots, or purulent material. Attempt to milk and/or strip the tubing, as described previously. Obtain a chest radiograph to determine if the chest tube is kinked. Twist the chest tube 180° and release it. If it spins back into its original position, it is kinked.⁷⁹ Remove the chest tube and insert a new one if the occlusion cannot be dislodged or the tube is kinked.

Subcutaneous emphysema results from air from an inadequately decompressed pneumothorax that tracks into the subcutaneous tissues or a misplaced chest tube.⁶² Ensure that the chest tube, drainage system, and suction source are functioning properly. Replace any component that is not functioning. Verify that the chest tube is within the pleural cavity and not within the subcutaneous tissues using either plain chest radiography or ultrasound.⁸⁰ Evaluate the chest radiograph to ensure that all of the distal drainage holes are within the pleural cavity and not in the subcutaneous tissues.

Reexpansion pulmonary edema occurs from the rapid expansion of a lung that has been collapsed for over 48 to 72 hours or from the removal of a large pleural effusion.^{4,81} Patients will begin to experience increasing shortness of breath and hypoxemia within a few hours of the procedure. Repeat chest radiographs

will show an expanded lung with pulmonary edema. The exact etiology of this complication is unknown. This complication may be prevented by the slow expansion of a lung and the removal of pleural fluid in increments. Treatment includes supportive care, supplemental oxygenation, and positive-pressure ventilation (e.g., bilevel positive airway pressure, continuous positive airway pressure, and/or intubation). Diuretics have no role in relieving the edema. Reexpansion pulmonary edema has an associated mortality rate of up to 20%.⁴

The sources of pain for a patient with a tube thoracostomy are numerous. These include the skin incision, subcutaneous dissection, intercostal muscle transection, the chest tube, and the underlying injury. Pain can usually be managed with a combination of oral, parenteral, and topical analgesics. Sedatives may be required but can often be avoided with adequate pain management. Intrapleural bupivacaine has been found to be effective in reducing pain.⁸²⁻⁸⁴ Administer 20 to 40 mL of 0.25% bupivacaine through the chest tube and into the pleural cavity. Clamp the chest tube or the tubing for up to 10 minutes to allow the bupivacaine to thoroughly coat the pleural cavity. **Carefully monitor and observe the patient to ensure that they do not develop a tension pneumothorax while the chest tube is clamped.** Unclamp the chest tube and allow the excess anesthetic to drain into the collection system. This can provide several hours of pain relief to a patient who may have limits or contraindications to parenteral analgesics.

SUMMARY

Tube thoracostomy is useful in the treatment of thoracic injuries resulting in chylothoraces, empyemas, hemothoraces, hydrothoraces, and pneumothoraces. Attention must be paid to observe sterile technique, choose the proper insertion site, carefully enter the pleura, and verify entry via digital examination. Employ appropriate drainage systems to assure maintenance of a closed, water-tight system. Monitor the patient regularly while the chest tube is in place. Emergency Physicians performing this procedure should be cognizant of the serious complications that may be associated with tube thoracostomies, some of which are directly related to the insertion technique. Adherence to the principles described above will assist in avoiding many of these complications and provide optimal care for victims of thoracic trauma.

Thoracentesis

Marianne Juarez and Jacqueline Nemer

INTRODUCTION

Thoracentesis is a term derived from the Greek meaning “to pierce the chest.” It is used today to refer to the removal of air or fluid from the thoracic cavity. Hippocrates first described thoracentesis in the management of an empyema.¹ Thoracentesis was widely used in World War II and the Korean conflict in lieu of a thoracotomy for chest drainage. This practice was replaced by tube thoracostomy by the time of the Vietnam War. Thoracentesis is used today in the diagnosis and therapy of pleural effusions, as an emergent and temporizing treatment of a tension pneumothorax, and in the management of small nontraumatic pneumothoraces.¹⁻⁴ Thoracentesis is generally indicated to aid in the evaluation and management of the underlying etiology in newly discovered pleural effusions. **Accumulation of pleural fluid is not a specific diagnosis but rather a reflection of an underlying process.**

A pleural effusion may be identified clinically and radiologically. The patient may develop pain related to irritation of the parietal pleura, compromised pulmonary mechanics, or interference with gas exchange.³ The pain may be in the abdomen, chest, or ipsilateral shoulder. Cough is a common presenting symptom, although its mechanism is unclear. Dyspnea occurs secondary to the space-occupying effect of the fluid and alterations in gas exchange. Pleural effusions can reduce cardiac output in extreme cases. Physical examination findings will depend on the size and location of the pleural effusion. Tactile fremitus may be absent or attenuated. There may be dullness to percussion. Auscultation may reveal decreased breath sounds over the involved hemithorax.

Radiographic diagnosis of pleural effusions may be made by a posteroanterior (PA) chest radiograph when there is homogeneous opacification in the hemithorax, absent air bronchograms, and clouded vesicular vascular markings.⁵ The minimum fluid volume injected into cadavers to blunt the costophrenic angle was between 175 and 500 mL.⁶ Chest computed tomography (CT) scan will provide details of the pleural effusion, associated findings, location, and size. Several studies support the routine use of ultrasound (US) to identify pleural effusions and to guide the thoracentesis procedure.

A lateral decubitus film is often necessary and will determine whether the fluid is loculated or free-flowing if CT scan and US are not available. It will be helpful if one of the following signs are present on the PA chest radiograph: blurred contour of the diaphragmatic dome, clear costophrenic angle, elevated hemidiaphragm, or the gastric bubble seen more than 2 cm from the lung border in patients with left-sided pleural effusions.² US may be necessary in localizing effusions that are < 10 mm thick on the lateral decubitus film.⁷

The use of US can aid in the localization of pleural effusions that may be small or missed on plain chest films or distinguish between interpretations as possible pneumonia or atelectasis.⁸ Pleural fluid can be identified on US as a black hypoechoic area that appears darker than the surrounding diaphragm, liver, and lung.

Thoracentesis performed blindly has a high associated complication rate.⁹ US-guided thoracentesis allows the Emergency Physician to map the pleural effusion, choose the best site for thoracentesis, and reduce the rate of complications.¹⁰⁻¹⁴ US guidance is safe in assisting with thoracentesis in intubated and mechanically ventilated patients, both of which are high-risk populations for complications.^{12,15}

A pneumothorax may be simple or under pressure (i.e., a tension pneumothorax).¹⁶ A simple pneumothorax may present clinically with chest pain, dyspnea, hypoxia, and tachycardia.¹⁷ Physical examination may reveal decreased breath sounds on auscultation of the affected side. A tension pneumothorax classically presents with absent breath sounds on the affected side, hypotension, and tachycardia. Other symptoms may include an acute change in mental status, air hunger, cardiorespiratory arrest, chest pain, cyanosis, deviated trachea, diaphoresis, and hypoxia.¹⁴ Sometimes a patient with a tension pneumothorax may have a normal physical examination due to subtle auscultation findings often missed in a noisy Emergency Department. Tactile fremitus may be absent, and percussion is typically hyperresonant over the hemithorax with the tension pneumothorax. Thoracentesis to relieve a tension pneumothorax is based on the mechanism of lung injury, the patient's symptoms, and physical examination findings. Mechanisms of injury to the lung include chest trauma, instrumentation of the chest, mechanical ventilation, and spontaneous lung rupture.

There are two major indications for performing a thoracentesis.^{1-3,16,18} The first is for the evacuation of air for treating a simple pneumothorax and for the emergent temporizing treatment of a tension pneumothorax. The second is for the evacuation of fluid.

This may be done to help diagnose the etiology of a pleural effusion or for the treatment of a symptomatic pleural effusion.

PLEURAL EFFUSIONS

ANATOMY AND PATHOPHYSIOLOGY

The pleura is a serous membrane that covers the diaphragm, lungs, mediastinum, and thoracic cavity. The pleural space is a potential space between the lung and the thoracic cavity. A thin layer of fluid normally exists between the visceral pleura covering the organs and the parietal pleura covering the chest wall. This fluid acts as a lubricant.³ Pleural fluid originates from the interstitium, parietal capillaries, and visceral capillaries. Hydrostatic and oncotic forces govern the flow of fluid in the pleural space. These forces are summarized in **Figure 52-1**. Protein free fluid enters the pleural space from the parietal pleura and is absorbed by the visceral pleura in a healthy person. Small amounts of protein then leak into the pleural space. Approximately 10% of the pleural fluid and large proteins are removed by the lymphatics at a rate of up to 20 mL/h for each hemithorax.² Ventilation and muscular activity facilitate the action of the lymphatics.³ Alterations in pleural fluid homeostasis will lead to a pleural effusion or the pathologic collection of excess fluid between the visceral and parietal pleura.¹⁹ Hydrostatic changes result in protein-free effusions or transudates. Changes in oncotic pressure in the lung or pleura lead to effusions. The differential diagnosis of transudates and exudates is listed in **Table 52-1**.

INDICATIONS

Thoracentesis may be performed to relieve the patient's symptom of dyspnea or hypoxia. It is performed whenever a pleural effusion interferes with normal respiration, results in respiratory compromise, or results in hemodynamic compromise. Thoracentesis may be performed to remove pleural fluid for analysis to diagnose the etiology of the fluid (e.g., infection or malignancy).

CONTRAINDICATIONS

Absolute contraindications include an uncooperative patient or a patient who refuses to give informed consent for the procedure.²⁰ Uncooperative patients or patients with altered levels of

TABLE 52-1 Differential Diagnosis of Fluid Exudates and Fluid Transudates in the Pleural Space

Exudates	Transudates
Asbestos exposure	Atelectasis

consciousness who emergently need thoracentesis may require sedation for the procedure.

There are numerous relative contraindications to performing a thoracentesis. Patients receiving anticoagulants, with a known or suspected bleeding diathesis, or with thrombocytopenia have a significant risk of bleeding.^{2,20,21} Consider reversing the anticoagulant or the bleeding disorder prior to performing the thoracentesis. A small volume of pleural fluid may make the procedure difficult to perform and increase the risk of complications.²⁰ Patients undergoing positive-pressure ventilation (e.g., bilevel positive airway pressure, continuous positive airway pressure, or using mechanical ventilation) are at an increased risk of developing a pneumothorax and a tension pneumothorax.¹ Pleural adhesions (i.e., a loculated pleural effusion) may limit the amount of fluid obtained or require multiple thoracenteses to drain the fluid.¹ Drain loculated pleural effusions under US guidance. Avoid areas of cellulitis or other infections on the chest wall unless no alternate site can be identified.^{1,3} Unsupervised physicians with little or no experience should not perform this procedure, as the risk of complications is increased.²² Patients with chronic obstructive pulmonary disease are at increased risk for complications.

FIGURE 52-1. Schematic of pleural fluid homeostasis in a normal lung.

EQUIPMENT

■ DIAGNOSTIC THORACENTESIS FOR PLEURAL EFFUSIONS

- Sterile gloves and gown
- Face mask with a face shield or goggles
- Lidocaine, 1% or 2%
- Purple top (EDTA) collection tube
- Heparin, 1000 U/mL
- Atropine
- Alcohol pads
- Povidone iodine or chlorhexidine solution
- Gauze 4 × 4 squares
- Sterile drapes
- Sterile towels
- Sterile gloves
- Band-Aids
- 25 or 27 gauge needle
- 21 and 22 gauge needles, 1.5 inches long
- 10 mL syringes
- 50 mL syringe
- 18 or 20 gauge needle

■ THERAPEUTIC THORACENTESIS FOR PLEURAL EFFUSIONS

- The supplies listed above
- 16 to 18 gauge catheter-over-the-needle
- Three-way stopcock
- Connector tubing (connects to three-way stopcock and sterile container)
- Sterile container for pleural fluid
- 50 mL syringe
- Intravenous (IV) extension tubing

■ US GUIDANCE

- US machine
- 3.5 to 5.0 MHz phased-array US transducer
- Sterile US gel
- Sterile US transducer cover

Commercial kits are available to perform a thoracentesis (Figure 52-2). The kits are disposable, intended for single-patient use, and usually contain most of the required equipment. They save time in that the equipment does not have to be gathered and set up. Disadvantages include potential increased cost and limited equipment in the kit.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative and obtain a signed consent form.¹ The position of the patient can vary depending on their clinical condition. Place ambulatory and cooperative patients sitting up at the edge of a bed with their feet on the floor or a stool (Figure 52-3). Place the patient's head and arms on an elevated bedside tray. The patient's back should be as vertical as possible so that the lowest part of the hemithorax is posterior. This will ensure that the free-flowing fluid remains posteriorly.^{1-3,20}

One of three other positions are recommended in debilitated patients. Place the patient in the lateral decubitus position and lying on the side of the pleural effusion. The patient's back should be along the edge of the bed. The procedure will be performed in the midscapular line or the posterior axillary line. Place the ventilator-dependent patient into the lateral decubitus position and lying on the side with the pleural effusion.²³ Alternatively, place the ventilator-dependent patient supine and elevate the head of the bed as maximally as possible. The patient will be sitting with the assistance of the bed, and the procedure will be performed in midaxillary or posterior axillary line.³ Finally, place the patient supine and perform the procedure in the midaxillary or posterior axillary line. US may be required to locate the pleural fluid with the patient supine. **Sedation or paralysis may be needed for optimal positioning depending on the patient's clinical condition.**

Prepare the patient. Clean any dirt or debris from the skin. Identify the anatomic landmarks required to perform the procedure. View the chest radiograph or US imaging to estimate the amount of pleural fluid. Percuss from superior to inferior starting at the midscapular or posterior axillary line. **Choose a single interspace below the top of the dullness to percussion for aspiration.** US may be used to locate the fluid.^{6,20} US is comparable to CT for diagnosing and managing a pleural effusion.²⁴

Place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them during and after the procedure as an added level of precaution. Apply povidone iodine or chlorhexidine solution to the skin surface and allow it to dry. Apply sterile drapes around the site of the procedure. Have atropine at the bedside. It can be administered intramuscularly, intravenously, or subcutaneously to patients who develop symptomatic bradycardia during the procedure. Don personal protective equipment to protect from contact with the patient's blood and body fluids as well as protect the patient from an iatrogenic infection.

Prepare the US transducer if using US with the procedure. Have an assistant apply US gel over the footprint of the transducer. Instruct the assistant to place the gel-coated US transducer in the sterile cover while you hold it. Have the assistant place sterile US gel on the patient or the covered transducer.

Place a skin wheal of local anesthetic solution over the thoracentesis site using a 25 or 27 gauge needle on a 10 mL syringe. Remove the 25 or 27 gauge needle from the syringe. Apply a 21 or 22 gauge, 1.5 to 3.0 inch needle to the syringe containing the local anesthetic solution. Anesthetize the subcutaneous tissues and the periosteum along the superior aspect of the rib (Figure 52-4). Walk the needle up the rib while simultaneously injecting local anesthetic solution. Gently aspirate prior to injecting each time the needle is advanced to ensure that the needle is not injecting within a blood vessel. Slowly and carefully advance the needle over the rib while applying negative pressure on the syringe when the superior border of the rib is located. **Be sure not to insert or advance the needle below the rib to avoid injury to the neurovascular bundle inferior to the rib.** Fluid will flow into the syringe when the pleural space has been entered. Inject and aspirate small volumes (e.g., 1 to 2 mL) while the needle is within the pleural cavity. This will distribute the local anesthetic solution into the pleural fluid and ensure anesthesia of the pleura. Withdraw the needle from the pleural cavity and out of the skin. Hold pressure to the skin puncture site to tamponade any bleeding.

DIAGNOSTIC THORACENTESIS TECHNIQUE FOR PLEURAL EFFUSIONS

Attach an 18 gauge needle to a 50 mL syringe. Introduce the needle through the anesthetized track and into the pleural cavity (Figure 52-5B). Aspirate up to 50 mL of fluid. Withdraw the

needle and place the fluid into the appropriate sterile containers. One of the containers should be a purple top (EDTA) collection tube to obtain a cell count and differential. An alternative is to collect the sample in a 50 mL syringe containing 1 mL of heparin (1000 U/mL) to ensure accurate cell counts, accurate pH, and prevent the fluid from clotting. **Use proper techniques when**

transferring the fluid into containers or specimen tubes to prevent a needlestick injury.

A “dry tap” occurs if pleural fluid cannot be aspirated. Consider that the needle may be too short to reach the fluid, positioned too high to reach the fluid (**Figure 52-5A**), positioned too low to reach the fluid (**Figure 52-5C**), or that there may not actually be

an effusion. Repeat the physical examination and review the chest radiograph to reconfirm the presence of a pleural effusion. Use US, if available, to assess for the presence of a pleural effusion. Penetration of the lung with the needle is rarely catastrophic but can result in a pneumothorax.³

The principles are the same for debilitated patients except the site for the procedure. Use the midaxillary or posterior axillary line if the patient is supine. **Be cautious of the diaphragm as it can be as high as the fifth interspace on expiration at the anterior axillary line.** Use the midscapular line or the posterior axillary line if the patient is in the lateral decubitus position.

THERAPEUTIC THORACENTESIS TECHNIQUES FOR PLEURAL EFFUSIONS

The same sterile preparation, location of fluid, positioning, and anesthesia considerations apply for therapeutic thoracentesis. **The main difference between a diagnostic and therapeutic thoracentesis is the quantity of fluid removed.** Up to 1.5 L is removed in a therapeutic thoracentesis. A diagnostic thoracentesis requires approximately 10 to 20 mL of pleural fluid.

■ CATHETER-OVER-THE-NEEDLE TECHNIQUE

The catheter-over-the-needle (i.e., angiocatheter) technique is most commonly used to perform a therapeutic thoracentesis (Figure 52-6). Make a small “nick” in the skin with a #11 surgical

blade at the anesthetized needle insertion site. Attach a 14 to 18 gauge catheter-over-the-needle to a 10 mL syringe as a handle. Insert the catheter-over-the-needle into the nick and advance it along the anesthetized tract (Figure 52-6A). Apply negative pressure to the syringe as the catheter-over-the-needle is advanced. Stop advancing the catheter-over-the-needle when fluid is aspirated. Angle the catheter-over-the-needle caudally. Securely hold the syringe and needle so they do not move. Advance the catheter until the hub is against the skin (Figure 52-6B). Withdraw the needle and syringe as a unit while the catheter remains in the pleural cavity (Figure 52-6B). **Quickly cover the catheter with a gloved finger when the needle is removed. This will prevent ambient air from entering the pleural cavity.** Attach IV catheter extension tubing to the hub of the catheter. Place a three-way stopcock attached to a 50 mL syringe onto the extension tubing. Hold the catheter hub against the skin securely. Aspirate fluid into the syringe and then advance the fluid into the sterile container by adjusting the three-way stopcock.

An alternative option is to set up a siphon through the three-way stopcock (Figure 52-7). Prime the tubing with pleural fluid. Place the end of the tubing into a sterile container that is located below the site of the catheter. Alternatively, apply a needle onto the end of the IV tubing and insert it into a suction container. This allows the fluid to flow freely into the sterile container. Fluid can be removed in 50 mL aliquots up to 1.5 L. Limit the amount removed to 1.5 L due to the risk of postevacuation pulmonary edema and excessive protein loss.¹

FIGURE 52-3. Recommended positioning of an ambulatory patient for a diagnostic or therapeutic thoracentesis for the evacuation of fluid.²

■ SELDINGER TECHNIQUE

An alternative approach is to use the Seldinger technique to insert a small-bore catheter into the pleural cavity. The major disadvantages to this technique include the time it takes to insert the catheter, the

FIGURE 52-4. Administration of local anesthesia. A skin wheal is made. The needle is inserted through the skin wheal, while local anesthetic solution is injected to anesthetize the subcutaneous tissues and the periosteum of the rib. The needle is “walked” above the upper border of the rib (red jagged line) to avoid the neurovascular bundle inferior to the rib. The intercostal muscles, parietal pleura, and pleural space are then infiltrated with local anesthetic solution.

FIGURE 52-5. Needle positioning for a diagnostic thoracentesis. **A.** The pleural space is entered above the effusion (too high). **B.** The pleural space is entered properly, over the rib and into the fluid. **C.** The needle is too low and enters the abdominal cavity below the diaphragm.

cost of the catheter kit versus a catheter-over-the-needle, and catheter blockage (e.g., from cells, debris, and protein) requiring insertion of a second catheter. Another option is to use a central venous catheter kit as the larger catheter opening may not become obstructed as easily.^{25,26} Refer to Chapter 63 for the complete details regarding using a central venous catheter and the Seldinger technique.

■ ULTRASOUND-GUIDED TECHNIQUE FOR PLEURAL EFFUSIONS

US can be used to map the location and the extent of a pleural effusion.^{27,28} It will help identify the appropriate site of needle entry. A 3.5 to 5.0 MHz phased-array transducer or 7.5 to 10 MHz high-frequency linear transducer is recommended.²⁹ Orientation of the transducer follows the convention that the marker should correlate to the reference point in the left upper corner of the monitor screen.

Percuss and auscultate the posterior thorax to estimate the location of pleural fluid with the patient in an upright sitting position. Apply sterile US gel onto the US transducer cover. Place the transducer at the intercostal space of the estimated level of pleural fluid in the posterior axillary line, usually at the level of ribs 9 to 11. Sweep the transducer inferiorly, superiorly, and transversely to assess the

FIGURE 52-6. The catheter-over-the-needle technique. **A.** The needle and catheter are inserted over the rib and aimed slightly caudally into the pleural cavity. **B.** The catheter is advanced into the pleural cavity, and the needle is removed.

FIGURE 52-7. Equipment for continuous pleural fluid drainage includes a stopcock, IV tubing, empty evacuated suction container, syringes for anesthesia and fluid collection, catheter-over-the-needle, and an 18 gauge needle.

location and size of the fluid collection. Identify the liver on the right, the spleen on the left, and the diaphragm.

Place the US transducer in the midscapular line or, if possible, the posterior axillary line to locate the fluid in a debilitated patient in the lateral decubitus position. Place the ventilator-dependent patient in the lateral decubitus position. Place the transducer in the posterior or midaxillary line if the patient is supine. **The movement of the diaphragm can be used as a key reference point when examining the pleural space.**³⁰ The liver may be used as an echogenic reference point for the identification of adjacent hyperechoic or hypoechoic structures. **The best window to view the intrathoracic contents is through the intercostal space as US penetration through the soft tissues is superior to that of rib bone or rib cartilage.**

The US waves will penetrate the skin, subcutaneous tissue, and muscle to produce multiple layers of varying echogenicity. The echogenic ribs cast an acoustic shadow (**Figure 52-8**). The parietal and visceral pleura are encountered posterior to the rib as two hyperechoic lines < 2 mm thick.^{30,31} The diaphragm is identified as a hyperechoic transverse structure at the base of the chest wall. The lung is visualized as a bright, hyperechoic structure just cephalad to the diaphragm. The lung becomes more intensely hyperechoic or brighter during inspiration. A pleural effusion is identified as an anechoic to hypoechoic image above the diaphragm that decreases in size with inspiration (**Figure 52-9A**). The lung swings during the respiratory cycle in the pleural effusion (**Figure 52-9B**).

Two additional US findings should be identified on examination. The movement of the lung to the surrounding parietal pleura with inspiration and expiration produces an artifact referred to as “lung slide” or the “seashore sign” (**Figure 52-10**).³² Normal inspiration produces a “slide” with each breath. This represents movement between the visceral and parietal pleural interface. The thin, hyperechoic sliding line is located approximately 0.5 cm below the surface of the rib and should move back and forth with each inspiration.³³

FIGURE 52-8. Ultrasound image of a normal lung. Visualized from top to bottom are the subcutaneous tissues, muscle (M), rib shadow (arrowhead), and pleural line (arrows).

A “comet tail artifact” is another normal finding that can be readily identified in a healthy patient (**Figure 52-11**).³² The comet tail artifact is identified as a hyperechoic vertical artifact that slides transversely and is oriented perpendicular to the transverse “lung slide.”³³

A pleural effusion is easily visualized using US (**Figure 52-9**). It appears black or anechoic. A distinct hyperechoic pleural line is not seen as the parietal and visceral pleura are separated by the effusion. Lung tissue appears hyperechoic compared with the anechoic effusion (**Figure 52-12**). The pleural effusion can be seen moving during the respiratory cycle.

The posterior approach is the preferred choice in the stable, cooperative patient who sits upright and leans over a table (**Figure 52-13**). Scan the posterior hemithorax from the inferior border of the scapula to the upper lumbar region and from the paravertebral area to the posterior axillary line to survey the lung anatomy and map the effusion. Note the minimum depth of the effusion and the location of other vital structures (i.e., diaphragm, liver, lung, and spleen). Scan with the transducer perpendicular to the ribs and observe the structures during the full respiratory phase. The diaphragm can go as low as the twelfth rib posteriorly and as high as the eighth rib laterally. Determine the location of the skin entry site. Mark the site with a pen, surgical marker, or by indenting the skin with the cap of a needle. **The ideal site should have a large area of pleural effusion and be free of any internal structures (i.e., liver, spleen, or diaphragm) along the needle path.**

The lateral approach is used for mechanically ventilated patients and for those unable to sit up for the procedure. Abduct the ipsilateral arm and place the hand behind the patient’s head (**Figure 52-14**). Survey the anterior and lateral thorax with US from the midclavicular line to the posterior axillary line. Note the depth of the effusion and the location of any vital structures to be avoided. Determine and mark the skin entry site.

A

B

FIGURE 52-9. Ultrasound image of a pleural effusion. **A.** The pleural effusion appears black or anechoic (*asterisks*). The pleura is not brightly echogenic (*arrows*) due to the separation of the two layers. Note the rib shadow (*arrowhead*) in the upper part of the image. **B.** Sinusoidal sign of lung movement in the pleural fluid during respiration. (Photo used with permission from Turner JP et al: Thoracic ultrasound. *Emerg Med Clin N Am* 2012; 30:451-473.)

The lateral decubitus approach is an alternative for patients unable to sit upright. Place the patient on their side with the pleural effusion side down. Use US to map the effusion. Note the distance from the skin to the effusion, the depth of the effusion, and the presence of any important structures to be avoided. Determine and mark the skin entry site.

Do not allow the patient to move once they have been scanned and the skin entry site marked regardless of the patient position or approach. Prep and drape the patient similar to that for the blind thoracentesis approach. Use local anesthetic to anesthetize the skin, rib, and pleura. The catheter-over-the-needle can be inserted using US guidance or blindly as described previously.

FIGURE 52-10. The sliding lung or seashore sign. Real-time US (*left*) and M-mode Doppler US (*right*). The *arrows* are the pleural interface. (Used with permission from reference 32.)

The use of US guidance can be helpful. Place a sterile cover over the US transducer and apply sterile US gel over the cover. Rescan the patient in the area previously identified as the skin entry site (**Figure 52-15**). Verify that no structures are along the needle path between the skin and the pleural effusion. Insert an 18 gauge catheter-over-the-needle into the pleural space using the technique already described while using US for visualization of the needle entering the pleural cavity. The needle will appear as a thin, bright, hyperechoic structure moving through the skin, subcutaneous tissue, parietal pleura, visceral pleura, and finally reaching the hypoechoic pleural effusion (**Figure 52-16**). Aspirate to confirm that the catheter-over-the-needle is within the pleural effusion. Place the US transducer aside. Continue the remainder of the procedure as described previously.

ASSESSMENT

Numerous analyses of the pleural effusion fluid are required to determine its etiology (**Tables 52-2 and 52-3**).³⁴ Large pleural effusions are more commonly associated with infections and

FIGURE 52-11. The lung rockets or comet tail artefacts. (Used with permission from reference 32.)

FIGURE 52-12. Ultrasound image of a pleural effusion (asterisks) with the underlying hyperechoic lung tissue (L). Note the rib shadow (arrowhead) in the upper left of the image.

malignancy.³⁵ Fluid analysis criteria have been established to separate transudates and exudates.¹⁰ An exudate is present if the fluid fits one of the criteria in **Table 52-4**.³⁶ These parameters have been confirmed to have 98% sensitivity and 83% specificity in detecting exudates.³⁷ Color and odor can be helpful. Consider an infection if the fluid has a putrid odor. White or yellow fluid suggests an empyema or chylothorax. The white blood cell (WBC) count is of limited benefit. The fluid likely represents a parapneumonic effusion if the

FIGURE 52-13. Posterior approach in the sitting patient. A linear ultrasound transducer is seen here, although a phased-array transducer is often preferred to visualize deeper structures.

FIGURE 52-14. Lateral approach in the supine patient. A curvilinear transducer is positioned in the midaxillary line. Note the coronal plane of the transducer.

WBC count is $> 10,000$. A pleural fluid hemoglobin and hematocrit can be compared to that of the blood. Bloody pleural effusions are usually associated with malignancy, pneumonia, pulmonary embolism with a lung infarction, or trauma.³⁸ Consider a hemothorax if the fluid is grossly bloody. A hemothorax is likely and consider chest tube placement if the pleural fluid's hematocrit is $> 50\%$ of the serum hematocrit. Other helpful tests include a fluid pH. A pH below 7.25 to 7.30 is usually the result of an esophageal rupture, malignancy, parapneumonic process, or rheumatologic process. An elevated amylase level suggests esophageal rupture, malignancy, or pancreatic disease.³⁹ Elevated triglyceride levels suggest a chylothorax. Cytology is important to search for an underlying malignancy.³ Bacteriologic information (e.g., Gram stain, acid-fast stain, and fungal stains) is important although the yield can be below 30%.²⁰

FIGURE 52-15. The pleural effusion (asterisks) is visible above the diaphragm (arrows). The liver (L) is seen below the diaphragm.

Pleural fluid LDH > 2/3 upper limit of normal for serum	

Always send the fluid for aerobic and anaerobic cultures to rule out an infectious etiology for the pleural effusion. The appearance of pleural fluid on US may help identify whether the pleural fluid is a transudate or exudate. Transudates are consistently seen as anechoic, whereas exudates may range from anechoic to hyperechoic.^{40,41}

AFTERCARE

Remove the catheter and apply a bandage to the puncture site when done aspirating fluid. Obtain a plain chest radiograph to assess for a pneumothorax. Repeat the chest radiograph in 4 to 6 hours to assess for a delayed pneumothorax.^{42,43} An expiratory film is the best option to look for a pneumothorax, especially if it is small. Discharge the patient with good instructions and close follow-up if no pneumothorax is present and if appropriate for the clinical condition.

Instruct the patient to evaluate the procedure site two to three times a day for signs of infection. Educate the patient about the signs, symptoms, and significance of an infection. They should return to their Primary Physician or the Emergency Department immediately if they develop any concerns, fever, chills, shortness of breath, redness, or pus at the puncture site.

COMPLICATIONS

The potential complications of a thoracentesis are listed in **Table 52-5**.^{1,3,11,20,22,37,44-47} Most studies report lower rates of postprocedural pneumothoraces with US-guided thoracentesis performed by an experienced operator.^{9-11,15,48-54} Other studies have not shown a significant difference in the incidence of postprocedural pneumothoraces with the use of US.^{55,56}

The use of the proper technique and Emergency Physician experience are important in reducing the rate of complications.^{53,57-60} It is difficult to predict which patients may be at risk of developing a postprocedural pneumothorax.⁶¹ Drainage of large volumes of fluid (i.e., greater than 1.5 to 2 L) may increase the risk of developing excessive protein loss, a pneumothorax, and reexpansion pulmonary edema.^{1,62,63} Improper technique or tortuosity of the intercostal artery can result in intercostal artery injury.^{64,65} Direct supervision of inexperienced operators, removal of small amounts of fluid, use of small-gauge needles, use of US for small effusions, and use of a needle-catheter system for a therapeutic procedure may all reduce the risk of an associated pneumothorax.²⁰

PNEUMOTHORAX

ANATOMY AND PATHOPHYSIOLOGY

A thoracentesis can be performed to relieve a simple pneumothorax or a tension pneumothorax.¹⁶ A pneumothorax is the presence of air between the visceral and parietal pleura.^{16,17,33,66} Primary spontaneous pneumothoraces occur in otherwise healthy people without antecedent trauma. Secondary spontaneous pneumothoraces occur as a complication of underlying lung disease, most commonly chronic obstructive pulmonary disease.^{1,3} A traumatic pneumothorax occurs from penetrating or blunt trauma to the thoracic cavity. An iatrogenic pneumothorax is a subcategory of the traumatic pneumothorax. The three most common etiologies for an iatrogenic pneumothorax are pleural biopsy, subclavian vein catheterization, and thoracentesis.⁶⁷

The pressure in the pleural space is negative compared to the atmosphere. This causes the lung to collapse and the chest wall to expand. The alveolar pressure is greater than the pleural space pressure due to the elastic recoil of the lung. A communication between the alveolar and pleural space allows the air to preferentially move into the pleural space until the pressure equalizes. The physiologic consequence is a decrease in vital capacity and PaO_2 . This may be well tolerated in healthy people but not in patients with underlying cardiac and/or pulmonary disease.

A one-way valve may allow air to enter the pleural space from the alveolus but not return. The intrapleural pressure will eventually exceed atmospheric pressure. A progressive increase in air

occupying the pleural space leads to a tension pneumothorax. Clinical deterioration may occur due to a decreasing PaO_2 , decreasing cardiac output, hypercarbia, and hypoxia.⁶⁸⁻⁷¹

US guidance may aid in locating a pneumothorax, with the best viewing window being the intercostal space.^{72,73} US can diagnose a pneumothorax within only 2 to 5 minutes compared to 20 to 30 minutes for chest radiography.^{72,74} US showed a sensitivity and specificity of 100% and 94% for detection of pneumothoraces, compared to 36% and 100% for chest radiography, respectively.⁷⁵

The presence or absence of lung sliding can be shown using M-mode Doppler US (**Figure 52-17**).⁷⁶ The lung normally shows “waves on a beach” or the “seashore.” The anterior chest wall is stationary and is represented by a line. The presence of lung motion posteriorly is represented by an irregular and granular pattern. M-mode Doppler US of a pneumothorax is represented by repeating horizontal lines from the lack of lung sliding. This is known as the “barcode sign” or the “stratosphere sign.”⁷⁶

Controversy exists regarding the exact management of a spontaneous pneumothorax.⁷⁷⁻⁸³ Options include simple aspiration, tube thoracostomy, simple aspiration followed by a tube thoracostomy if aspiration fails, and outpatient versus inpatient management. Simple aspiration is more likely to fail with larger pneumothoraces.^{77-81,84} These studies noted that simple aspiration is associated with a reduction in the percentage of patients requiring hospitalization compared to tube thoracostomy. There were no differences between the two procedures in early failures, immediate success rates, duration of hospitalization, 1-year success rates, and the number of patients requiring a subsequent pleurodesis. Advantages of simple aspiration compared to tube thoracostomy include less equipment costs, easier and quicker to perform, and the potential to avoid hospitalization.

The size of a pneumothorax can be calculated in three ways.^{61,85-87} Collins calculated the size as follows: size (%) = $4.2 + 4.7$ (distances at apex + midpoint of the upper half of the collapsed lung + midpoint of the lower half of the collapsed lung).⁸⁷ The calculation was derived from helical CT scan data. It uses the distances determined on a PA chest radiograph and may overestimate the size of a large pneumothorax. Light determined the volume as follows: volume (%) = $100 - [(average\ diameter\ of\ lung)^3 \div (average\ diameter\ pneumothorax)^3 \times 100]$.⁶¹ This calculation uses the distances determined on a PA chest radiograph and may underestimate the size of a small pneumothorax. It is accurate for medium and large pneumothoraces. Rhea calculated the size as follows: size = (distances at apex + midpoint of the upper half of the collapsed lung + midpoint of the lower half of the collapsed lung) $\div 3$.^{85,86} The pneumothorax size is converted to a volume using a normogram. It uses the

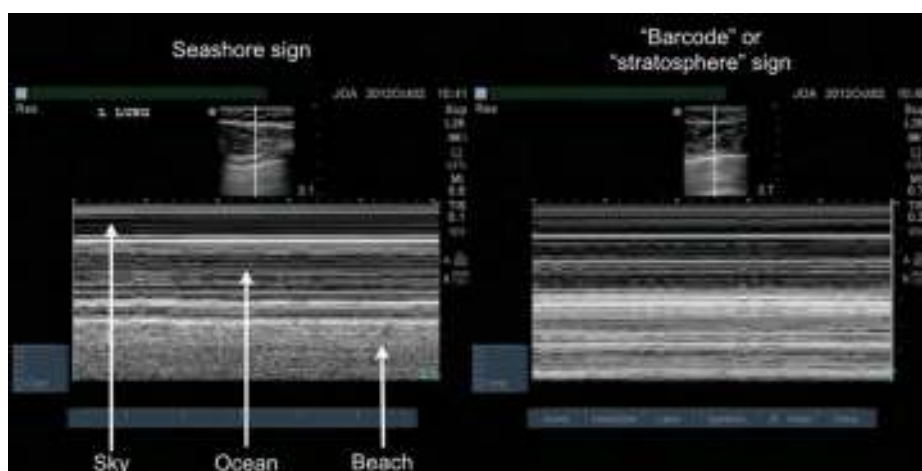

FIGURE 52-17. The normal US versus a pneumothorax. (Courtesy of Jacob Avila, MD, and www.5minsono.com.)

distances determined on a PA and lateral chest radiograph. It may underestimate the size of a large pneumothorax.

INDICATIONS

All tension pneumothoraces require needle drainage (Chapter 50) followed by tube thoracostomy (Chapter 51). Patients usually present with hypotension, neck vein engorgement, respiratory distress, tachycardia, and unilateral absence of breath sounds. These patients have tracheal deviation that is often difficult to assess and is often limited to the thoracic cavity.

Not all simple pneumothoraces require drainage as they may resolve spontaneously. A small pneumothorax in a healthy patient may be treated conservatively with observation alone which has shown a spontaneous resorption rate of 1.25% a day.⁶⁰ The application of supplemental inhaled oxygen can facilitate reabsorption of air in the pleural cavity up to fourfold faster.⁸⁸ Drain a pneumothorax if the patient complains of dyspnea, dyspnea on exertion, or pain, or if the pneumothorax is estimated to be 15% or greater.^{83,89}

CONTRAINDICATIONS

There are no absolute or relative contraindications to relieving a tension pneumothorax since it is a life-threatening emergency.

Contraindications to thoracentesis to relieve a simple pneumothorax are few.⁸⁹ Select an alternative site if the primary site has an infection.³ A traumatic pneumothorax or a pneumothorax associated with a hemothorax or empyema requires a tube thoracostomy. Any pneumothorax that is expanding or expanding despite thoracentesis requires a tube thoracostomy. Any patient on anticoagulation or with a possible bleeding diathesis may require reversal of the condition before the procedure.¹ A patient with minimal symptoms and a small pneumothorax may be observed before deciding to evacuate the pneumothorax.

EQUIPMENT

■ PNEUMOTHORAX—TENSION

- Alcohol swab, povidone iodine solution, or chlorhexidine solution
- 12 to 16 gauge catheter-over-the-needle, 2 inches long

■ PNEUMOTHORAX—STABLE

- Sterile gloves and gown
- Face mask with a face shield or goggles and cap
- Povidone iodine or chlorhexidine solution
- Sterile gauze sponges
- Sterile towels
- Sterile basin
- Syringes for anesthesia infiltration, 5 and 10 mL
- 25 gauge needle for anesthesia infiltration of the skin
- 21 or 23 gauge needle for infiltration of subcutaneous tissue, periosteum, and pleura
- 16 or 18 gauge catheter-over-the-needle
- Pigtail or straight catheter kit
- Three-way stopcock
- 50 mL syringe
- Intravenous extension tubing
- Heimlich valve

■ US GUIDANCE

- US machine
- 3.5 to 5.0 MHz phased-array US transducer
- 7.5 to 10 MHz high-frequency linear US transducer
- Sterile US gel
- Sterile US transducer cover

Commercial kits have been developed and are available to provide the equipment needed to perform a thoracentesis (**Figure 52-2**). These kits are disposable, single-patient use, and contain all the required equipment. They save time in that the equipment does not have to be found and set up. Disadvantages include potentially increased cost and limited equipment in the kit.⁶⁸

Some alternative devices exist that combine the pigtail catheter and Heimlich valve in the same kit. They use a one-piece unit that combines an intrapleural catheter and an external one-way antireflux valve that attaches to the chest wall by an adhesive pad. Its insertion is quicker, easier, and simpler than a traditional catheter. The low profile makes ambulation and outpatient management easier for the patient. These devices are rarely available in the Emergency Department.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative and obtain a signed consent form.¹ Place the patient supine on the bed. Alternatively, the patient may be supine with the head of the bed elevated to 30° (**Figure 52-18**). Clean any dirt or debris from the skin. Identify the anatomic landmarks required to perform the procedure. It is recommended to place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen, although not required. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Apply sterile drapes around the site of the procedure. Have atropine available at the bedside. It may be administered intramuscularly, intravenously, or subcutaneously to patients who develop symptomatic bradycardia during the procedure. The most common approach is the second intercostal space in the midclavicular line (**Figure 52-18**). An alternate site is the fourth or fifth intercostal space in the midaxillary line. Don full personal protective equipment to protect from contact with the patient's blood and body fluids as well as protect the patient from an iatrogenic infection.

FIGURE 52-18. Relief of a tension pneumothorax. Place the patient supine with the head of the bed elevated 30° if not contraindicated. The second intercostal space in the midclavicular line is the recommended site. For pleural effusions or a debilitated patient, the midaxillary line or posterior axillary line may be used at the level of the fourth or fifth intercostal space.

TENSION PNEUMOTHORAX TECHNIQUE

Thoracentesis is a diagnostic and therapeutic procedure if the patient has a tension pneumothorax. A tension pneumothorax is a true life-threatening condition. Identify the needle insertion site by palpating the second intercostal space in the midclavicular line. US guidance is not necessary prior to needle decompression and should not delay treatment if a tension pneumothorax is clinically evident. **Insert the catheter-over-the-needle over the superior border of the third rib to avoid the neurovascular bundle located on the inferior border of the second rib.**¹⁶ Advance the catheter-over-the-needle into the pleural space. A 5 or 10 mL syringe without the plunger can be attached to the catheter-over-the-needle. The syringe barrel can be used as a handle to advance the catheter-over-the-needle.

A release of pressure and a small “pop” may be felt when the pleural cavity is entered. Stop advancing the needle. Securely hold the needle so it does not move. Advance the catheter until the hub is against the skin. Remove the needle. A continuous rush of air may be heard or felt if the patient has a tension pneumothorax. **Needle thoracentesis for a tension pneumothorax is a temporizing measure. Perform a tube thoracostomy (Chapter 51) immediately after this life-saving procedure.**⁹⁰

SIMPLE PNEUMOTHORAX TECHNIQUES

A primary spontaneous pneumothorax occupying over 15% of the hemithorax is the indication for simple aspiration via a thoracentesis.³ The same sterile preparation, location of fluid, positioning, anesthesia considerations, and US-guided technique apply to the evacuation of a simple pneumothorax as to a diagnostic thoracentesis. Spontaneous pneumothoraces used to be drained by tube thoracostomy; however, simple aspiration may be just as effective.⁷⁷⁻⁸²

■ CATHETER-OVER-THE-NEEDLE TECHNIQUE

The catheter-over-the-needle technique is most commonly used for drainage of a spontaneous pneumothorax (Figure 52-6). Anesthetize the site marked for needle insertion by making a small wheal under the skin. Make a small “nick” in the skin with a #11 surgical blade at the needle insertion site. Attach a 14 to 18 gauge catheter-over-the-needle to a 10 mL syringe as a handle. Insert the catheter-over-the-needle into the nick and advance it along the original anesthetized tract (Figure 52-6A). **Insert the catheter-over-the-needle over the superior border of the rib to avoid the neurovascular bundle located on the inferior border of the rib.**¹⁶ Apply negative pressure to the syringe as the catheter-over-the-needle is advanced. Stop advancing the catheter-over-the-needle when air is aspirated. Angle the catheter-over-the-needle superiorly. Securely hold the syringe and needle so they do not move. Advance the catheter until the hub is against the skin. Withdraw the needle and syringe as a unit while the catheter remains within the pleural cavity (Figure 52-6B). **Quickly cover the catheter with a gloved finger when the needle is removed. This will prevent ambient air from entering the pleural cavity.** Attach IV catheter extension tubing to the hub of the catheter. Place a three-way stopcock attached to a 50 mL syringe onto the extension tubing. Hold the catheter hub against the skin securely. Aspirate air into the syringe and then advance the air into the room by adjusting the three-way stopcock.

Air is withdrawn manually. Continue the process until resistance is felt. **It is presumed that reexpansion has not occurred and a continual leak of air exists from the lung into the pleural cavity if no resistance is felt after 2.5 L of aspiration. Perform a tube thoracostomy (Chapter 51).** Close the stopcock after no more air is aspirated and secure it to the chest wall. The success rate for the aspiration of a pneumothorax is approximately 60%.⁹¹⁻⁹³

■ SELDINGER TECHNIQUE

Drainage can be accomplished using a pigtail or straight catheter and the Seldinger technique (Figure 52-19). An alternative is to use a central venous catheter if a pigtail catheter is not available.^{68,94} Attach a 16 gauge, 2 inch catheter-over-the-needle to a 5 or 10 mL syringe. Insert the catheter, as described above, aimed superiorly. **Insert the catheter-over-the-needle over the superior border of the rib to avoid the neurovascular bundle located on the inferior border of the rib.**¹⁶ Securely hold the needle and syringe so it does not move. Advance the catheter to the hub. Remove the needle and syringe. **Quickly cover the catheter hub with a gloved finger.** Insert the guidewire through the catheter (Figure 52-19A). **Hold the guidewire securely to prevent it from falling completely into the pleural cavity.** Remove the catheter over the guidewire and leave the guidewire in place (Figure 52-19B). Extend the skin incision with a #11 scalpel blade by 3 to 5 mm to allow the catheter into the pleural space without “crumpling” (Figure 52-19C). Advance the dilator over the guidewire and into the pleural cavity to dilate the tract (Figures 52-19C and 19D). A gentle twisting motion of the dilator as it is advanced will aid in its insertion into the pleural cavity (Figure 52-19D). Hold the guidewire securely. Remove the dilator while leaving the guidewire in place. Insert the catheter over the guidewire and into the pleural cavity (Figure 52-19E). Remove the guidewire and attach a three-way stopcock to the catheter. Aspirate the air as described previously.

■ DRAINAGE SYSTEMS

Drainage systems for a pneumothorax vary in style but function with the same “one-way valve” principle. The simplest method is a flutter valve. It is best illustrated by the following noncommercial method. Cut a premoistened finger from a sterile glove. Tie the proximal end to the thoracentesis catheter with a silk suture and cut the distal end so that it is open to the air (Figure 52-20).¹ This creates a flutter valve and allows air to escape with coughing or expiration and prevents air from reentering the pleural space on inspiration.

Commercial kits are available that can be used for outpatient management of a pneumothorax in some patients. The kit often contains a Heimlich flutter valve (Figure 52-21).^{1,66} **The arrow on the clear protective tube covering the Heimlich valve must point away from the patient.**⁹⁵ Suction is usually not needed. Outpatient management may be considered in stable patients with a primary spontaneous pneumothorax that is small and apical with initial lung reexpansion and have good apposition of the lung with the lateral chest wall.⁹⁶ **The patient must be able to understand and comply with outpatient instructions, must have access to immediate help, and must return to an Emergency Department if symptoms arise.** Additional requirements include good residual lung function, normal oxygen saturation, and an air leak adequately treated by thoracentesis.²² **A contraindication to using the flutter valve is a hemothorax.** A closed underwater seal system is recommended in these cases. Refer to Chapter 51 for details regarding the use of a closed underwater seal system and the other indications for its use.

The Pneumostat (Maquet Getinge Group, Hudson, NH) is a single-use device (Figure 52-22). It attaches to a garment. The Pneumostat has multiple chest tube connectors. The air leak well provides quick and simple air leak confirmation. It has a 30 mL collection chamber and a needleless sampling port. It helps the patient ambulate sooner due to it being small and not cumbersome. It has a one-way valve for patient protection.

The TRU-CLOSE Thora-Vent (UreSil LLC, Skokie, IL) is an alternative device to the pigtail catheter and Heimlich valve combination (Figure 52-23). It is a one-piece unit that combines an intrapleural catheter and external one-way antireflux valve that attaches to the chest wall by an adhesive pad. Its insertion is quicker, easier,

FIGURE 52-19. The Seldinger technique for inserting a catheter to aspirate a pneumothorax. A catheter-over-the-needle has been placed into the pleural cavity and aimed superiorly. The needle has been removed while the catheter remains in the pleural cavity. **A.** A guidewire is inserted through the catheter. **B.** The catheter is removed while the guidewire remains in the pleural cavity. **C.** The skin incision is enlarged with a #11 scalpel blade. A dilator is placed over the guidewire. **D.** The dilator is advanced over the guidewire and into the pleural cavity. A gentle twisting motion will help guide the dilator through the tract. **E.** The dilator has been removed while the guidewire remains inside the pleural cavity. The catheter is advanced over the guidewire and into the pleural cavity. The guidewire is then removed while the catheter remains inside the pleural cavity.

and simpler than a traditional catheter. It is inserted using a trocar. The diaphragm is used to indicate pleural entry and pneumothorax resolution. The low profile makes ambulation and outpatient management easier for the patient. This device is rarely available in the Emergency Department.

■ ULTRASOUND-GUIDED TECHNIQUE FOR A PNEUMOTHORAX

The same sterile preparation applies to US evaluation of a pneumothorax as for evaluation of a pleural effusion. A pneumothorax may be more readily identified with the patient positioned supine rather than upright with US. A 3.5 to 5.0 MHz phased-array transducer or

7.5 to 10 MHz high-frequency linear transducer is recommended.²⁹ The orientation of the transducer follows the convention that the marker should correlate to the reference point in the left upper corner of the monitor screen.

The key US features of a pneumothorax include the absence of inspiration-expiration-related “lung slide,” loss of “comet tail” artifact, and broadening of the pleural line to a thick band (**Figure 52-17**).^{31,76} Compare the hemithorax suspected of having a pneumothorax to the unaffected side to confirm these findings in the case of a unilateral pneumothorax (**Figure 52-17**). Aspirate a pneumothorax using the US similar to a pleural effusion.⁹⁷

FIGURE 52-20. Use of a finger from a sterile glove as a one-way valve. Place the proximal end of the finger on the drainage system and cut the distal tip. It will act as a one-way valve.

Flow in direction of shaded arrow creates positive pressure within the tube, distending it and allowing air to escape

Flow in direction of shaded arrow creates negative pressure within the tube, collapsing it and preventing air escape

C

FIGURE 52-21. The Heimlich valve. **A.** Picture of the device. **B.** Schematic illustration. **C.** A collapsed tube is tethered within the rigid cylindrical chamber. Positive pressure within the tube distends it and allows air to flow outward. Negative pressure within the tube collapses it and prevents reversal of flow. (Part C used with permission from reference 95.)

ASSESSMENT

Relief of a tension pneumothorax will equalize the pressure between the atmosphere and the pleural space. The patient will now have a simple pneumothorax. The vital signs should begin to normalize and the respiratory distress improve. The patient will need a tube thoracostomy (Chapter 51) followed by a chest radiograph if they had a tension pneumothorax. The patient may begin to cough when

the lung expands. Breath sounds should be present bilaterally upon reexpansion.

There are two possibilities if the patient does not improve clinically after needle decompression for a tension pneumothorax. The pleural space may not have been entered with the needle. This occurs when the chest wall is thick (e.g., patient is obese or very muscular). The procedure may be repeated with a longer needle. The patient may not have had a tension pneumothorax. Reevaluate the patient by physical examination, bedside US, or review of the chest radiograph to determine if a tension pneumothorax is present.

Obtain a chest radiograph after the relief of a simple pneumothorax. It will allow the Emergency Physician to determine the success, or lack thereof, of the procedure. Perform a tube thoracostomy if at any point the pneumothorax is not improving with a thoracentesis or if the patient's symptoms worsen.

AFTERCARE

Obtain a follow-up chest radiograph upon completion of the procedure to assess for a pneumothorax. An expiratory film may be helpful, especially if the pneumothorax was small. Repeat the chest radiograph 4 to 6 hours after the procedure to look for a delayed pneumothorax. The patient may be discharged with good instructions and close follow-up if no pneumothorax is present and if

FIGURE 52-22. The Pneumostat.

A

B

FIGURE 52-23. The Thora-Vent. **A.** Kit. **B.** The device. (Photos courtesy of Uresil LLC.)

appropriate for their clinical condition.⁹⁸ An alternative is placement in an observation unit and discharge within 24 hours.

Instruct the patient to evaluate the procedure site two to three times a day for signs of infection. Educate the patient about the signs, symptoms, and significance of an infection. They should return to their Primary Physician or Emergency Department immediately if they develop any concerns, fever, chills, shortness of breath, redness, or pus at the puncture site.

A patient may be a candidate for outpatient management with a Heimlich valve if they have a stable primary spontaneous pneumothorax, close apposition of the lung to the lateral chest wall, Emergency Physician satisfaction with the position of the catheter, and an air leak that is manageable with one thoracentesis.⁹⁹⁻¹⁰⁷ Contraindications for outpatient management include a hemothorax, a large air leak requiring tube thoracostomy, poor residual function, secondary pneumothoraces, traumatic pneumothoraces, unacceptable

residual collapse defined as poor apposition of the lateral lung to the lateral chest wall, and unreliable patients.¹⁸

Instruct the patient to clean the thoracentesis site with mild soap daily, apply a split dressing around the catheter and tape it to the skin, make sure that the tubing is taped firmly to the valve to prevent accidental dislodgment, make sure the arrow on the valve points away from the patient, and make sure the sound of air exiting the valve is expected; showers are permitted, but not baths or swimming. Patients should call 911 and immediately return to the Emergency Department if they experience shortness of breath, chest pain, or difficulty breathing. **Instruct the patient on the removal of the Heimlich valve from the catheter if significant shortness of breath develops as they may have developed a tension pneumothorax.** Instruct the patient on the signs of an infection at the chest wall insertion site.

Arrange daily follow-up for radiographic evaluation. Remove the thoracentesis catheter upon complete inflation of the lung. Observe the patient for 4 to 6 hours after catheter removal and obtain a repeat chest radiograph. Discharge the patient if the lung is completely expanded. Perform a tube thoracostomy if the lung is not completely expanded.

COMPLICATIONS

Complications associated with this procedure can be numerous. A worsening pneumothorax may be caused by lacerating the lung with the needle, inadequate coverage of the hub of the needle or catheter with a gloved finger after entering the pleural space, an air leak in the drainage system, and a lung parenchymal-pleural fistula that can develop from poor lung expansion during large-volume pneumothorax drainage.¹⁰¹ Puncture of the lung can cause a pulmonary contusion.¹⁰² A tension pneumothorax can occur from a lung laceration along with inadvertent plugging of the drainage system (e.g., fluid in tube or kinking). A hemothorax is possible if the intercostal artery, lung, or mammary artery is lacerated with the needle.⁸⁹ Less common complications include cardiac or great vessel perforation due to poor positioning of the needle upon insertion. Infection occurs approximately 2% of the time if sterile technique is observed. Many of these complications can be prevented by using proper and careful technique. Aspiration of a pneumothorax can result in a recurrence and require a chest tube.^{16,93,103}

Reexpansion hypotension has been reported following rapid evacuation of persistent unilateral pneumothoraces of at least 1 week in duration.^{1,108} The mechanism is unclear. It is associated with reexpansion pulmonary edema that precipitates intravascular volume depletion, myocardial depletion, or large-volume aspiration.^{1,108} Reexpansion pulmonary edema may be precipitated by pneumothoraces over a few days in duration before reexpansion or large-volume aspiration.¹⁰⁴⁻¹⁰⁶

PEDIATRIC CONSIDERATIONS

Thoracentesis in pediatrics is similar to the adult (**Table 52-6**).¹⁰⁷ Most information is extrapolated from adults or small pediatric case studies. A pneumothorax occurs less frequently in pediatric patients than adults. A spontaneous pneumothorax is more often seen in males and teenagers. No single mechanism explains the etiologies of a spontaneous pneumothorax. No equations exist for estimating the size of a pneumothorax. The recurrence rate is unknown.

SUMMARY

A thoracentesis can help differentiate between pleural effusions that are transudates and exudates. Together with the clinical presentation, the information can be useful in diagnosing the patient's

Open Chest Wound Management

Eric F. Reichman

INTRODUCTION

Open chest wounds come in a variety of shapes and sizes. Their one commonality is an open communication between the pleural space and the external environment. The wounds have often been sealed by the soft tissues of the chest wall in the vast majority of patients with penetrating injuries to the chest. The primary concern with these patients is the diagnosis and treatment of underlying thoracic, cervical, and/or abdominal injuries. **Rarely, small perforations may produce a valve-like entry into the pleural space, enabling air to be “sucked in” during inspiration but blocking air egress during expiration.¹⁻³ Thus air will continue to accumulate, leading to a tension pneumothorax requiring needle decompression followed by a tube thoracostomy.** Larger, more destructive wounds of the chest may also occur. These are most common in combat injuries. In civilian practice, they are often secondary to shotgun injuries. The larger wounds are also caused by high-velocity weapons, explosions, on-the-job injuries, propeller injuries, or fencepost impalements, to name a few. Clothing, wadding, shell fragments, and pieces of the chest wall may all be driven into the thoracic cavity. Such injuries are associated with physical loss of a portion of the chest wall itself, making adequate ventilation impossible.^{4,5}

These wounds are known by numerous names including open chest wounds, open pneumothoraces, sucking chest wounds, and communicating pneumothoraces. These specific open chest wounds are the focus of this chapter.

Wounds of the chest are described in the earliest of medical documents, the Edwin Smith papyrus. This document dates from the time of Imhotep (3000 B.C.). During Greco-Roman times, open

chest wounds were universally fatal. Galen cared for chest wounds in gladiators. Treatment consisted of a poultice and leaving the wound open. This treatment did not change until the time of Theodoric in 1267 who advised the closing of chest wounds.

Techniques for managing chest wounds have improved with each subsequent war. The most important treatable aspect of these chest wounds was the associated open pneumothorax. The question of whether to manage such injuries open or closed remained controversial. John de Vigo, in 1514, was the first surgeon to present his views on gunshot wounds of the chest. He thought them to be universally fatal and, for the most part, untreatable. William Hewson, in 1767, observed that a patient with a large open chest wound was not able to breathe but could do so easily once the injury was closed. It took another 40 years for Baron Larrey, Napoleon's Surgeon, to confirm Hewson's observation in a wounded soldier. Another famous accounting of an open chest wound was by William Beaumont in 1825. He arrived within one-half hour of the injury and saved the patient's life by closing his chest wound.

By the final years of World War I, the controversy of “to close or not to close” was resolved in favor of immediate wound closure. However, when closing these wounds, it was important to understand the physiology of negative intrathoracic pressure. The German internist Buelau introduced closed underwater seal drainage of an empyema in 1875. In 1889, T. Holmes, a consulting Surgeon at St. George's Hospital in London, introduced intercostal drainage for large chest wounds. It was not until World War II that closed tube drainage was added to the treatment of an open pneumothorax as a routine measure. Positive-pressure ventilation was introduced in the early 1900s. The most recent advancement in the treatment of these injuries came from the Scandinavians, who invented respirators in the early 1950s. Mortality from chest wounds steadily decreased in each war. It was 79% in the Crimean War, 62.5% in the Civil War, 55.7% in the Franco-Prussian War, 24.6% in World War I, and 12% in World War II; in recent civilian experience, it is now 4% to 7%.⁵

ANATOMY AND PATHOPHYSIOLOGY

The pathophysiology of an open pneumothorax has not much been improved upon since the days of Hewson and Larrey. The pathophysiologic changes of a sucking chest wound depend on the size of the wound and the intactness of the pleural space and lung. A defect in the chest wall is usually of no major clinical significance if the pleural space is obliterated.⁶ However, most commonly, the pleural space is free and the air and/or blood moves in and out through the chest wall defect, making a “sucking” sound.

A sucking chest wound or open pneumothorax results in a unidirectional flow of air through the wound and into the pleural space. During inspiration, the intrathoracic pressure is negative compared to the extrathoracic pressure. This allows air to flow through the wound and into the pleural space. During expiration, the tissues surrounding the wound come into apposition and decrease the wound diameter. This results in air becoming trapped within the pleural space. As breathing continues, this process progresses and air increasingly accumulates in the pleural space, compresses the lung, and prevents lung expansion during inspiration. The open pneumothorax can become large enough to exert tension on the hemithorax contents and the mediastinal structures.

In larger injuries, this air movement causes the ipsilateral lung to move inward and collapse on inspiration (**Figure 53-1A**). The lung may expand slightly or remain completely collapsed upon expiration, depending on the size of the chest wall defect (**Figure 53-1B**). There may also be mediastinal motion toward the noninjured lung during inspiration and toward the injured lung during expiration. This to-and-fro motion compromises the function of the healthy lung as well as the injured lung because it prevents its full expansion

FIGURE 53-1. The effects of an open chest wound. **A.** Air moves into the pleural cavity and the lung collapses with inspiration. **B.** Air exits the pleural cavity and the lung expands slightly with expiration. The arrows represent the direction of airflow.

during inspiration. During expiration, some of the air from the noninjured lung may shift to the injured lung, and the reverse may happen during inspiration (an element of the “pendelluft” phenomenon). This entire mechanism results in a large functional dead space in the noninjured lung and loss of ventilation of the injured lung, causing severe ventilatory derangement, asphyxia, hypoxemia, and hypercarbia.⁵⁻⁷

The patient with an open pneumothorax may manifest a spectrum of presentations, ranging from asymptomatic and stable to severely dyspneic and agonal. The presentation depends on the size of the chest wall defect, the extensiveness of the injuries to the lung and other structures, the preinjury pulmonary status, and whether the pleural space is free or has adhesions. The patient may present with progressive respiratory insufficiency leading to a rapid demise if not treated. **The critical diameter of the chest wall wound has been described as two-thirds (or greater) the diameter of the trachea.⁸ It is thought that, at this size, air moves preferentially through the chest wall rather than through the trachea.**

Two additional open chest wounds deserve mention. First is the wound that fully penetrates the chest wall but seals itself and closes. It can seal from apposition of adjacent chest wall soft tissues, a hematoma, underlying pleural adhesions that do not allow air into the pleural space, or a combination of these. This type of injury prevents air from entering the pleural space and does not significantly alter respiratory physiology except for the pain of breathing. This

type of wound does not indicate that there is no underlying cardiac, intrathoracic, lung, or mediastinal injury. These types of wounds require management of hemorrhage, the application of a simple dressing, and a Surgeon for management of the wound, continued hemorrhage, and any internal injuries.

The final type of open chest wound is one that allows bidirectional airflow. Breathing results in bidirectional airflow through both the trachea and the chest wound, thus decreasing airflow through the trachea. This results in hypoventilation and hypoxemia. These patients require positive-pressure ventilation with either a bag-valve-mask device, continuous positive airway pressure, or bilevel positive airway pressure through a face mask or an endotracheal tube. The wound must be covered with a three-sided dressing or an occlusive dressing after the placement of a chest tube, and a Surgeon is required for management of the wound, continued hemorrhage, and any internal injuries.

INDICATIONS

Diagnosis of these injuries can be made easily based on the obvious presence of the chest wall defect and the noise produced as the air moves in and out through the wound. All open chest wounds should be treated immediately if the patient is symptomatic.^{6,9} Treatment techniques should be selected based on the patient’s clinical condition and stability (**Figure 53-2**). **The three-sided dressing is only a**

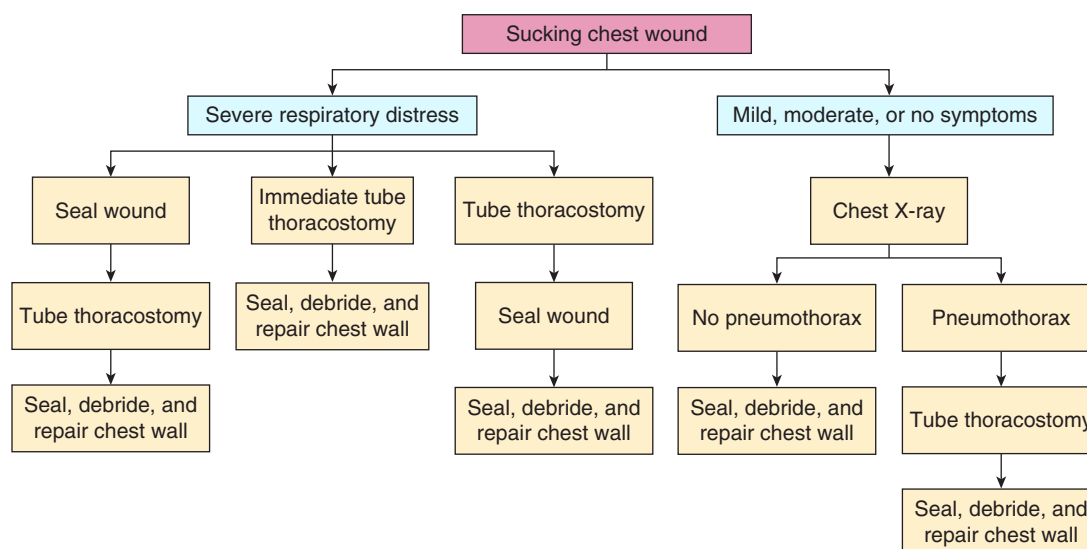

FIGURE 53-2. Algorithm for the diagnosis and treatment of an open pneumothorax. (Modified from reference 6.)

temporary measure, and it must be followed with the placement of a chest tube (Chapter 51). Current guidelines recommend leaving the open chest wound exposed and open or applying a nonocclusive dressing.¹⁰

Most experts agree that only the symptomatic patients should be treated in the field. An occlusive dressing should be placed over the wound and taped on only three sides. **The three-sided dressing allows air within the pleural cavity to be expelled into the atmosphere while preventing atmospheric air from entering the pleural cavity. If the wound is taped on all four sides, an open pneumothorax may quickly be converted into a tension pneumothorax.**^{7,8,11-14}

In the Emergency Department, the very symptomatic patient should be treated as in the field. However, a completely occlusive dressing may be placed over the wound if a tube thoracostomy is subsequently performed. Continuously and closely monitor the patient for the development of a tension pneumothorax if the wound is completely sealed prior to the tube thoracostomy. **If a tension pneumothorax occurs, remove the occlusive dressing on at least one side or perform a needle thoracostomy (Chapter 50) to relieve it.**

Obtain a rapid, portable anteroposterior chest radiograph if the patient is asymptomatic, mildly symptomatic, or moderately symptomatic. If a pneumothorax is present, perform a tube thoracostomy and seal the wound. If the patient becomes severely symptomatic, the Emergency Physician should default to the other limb of the algorithm (Figure 53-2).

CONTRAINDICATIONS

There are no contraindications to the placement of a three-sided occlusive dressing, as this is a treatment for a life-threatening emergency. It must be properly placed to prevent the accidental conversion to a totally occlusive dressing and the progression of an open pneumothorax to a tension pneumothorax.¹⁵ Likewise, current guidelines recommend not using an occlusive four-sided dressing.¹⁰

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Petrolatum gauze
- Gauze 4 × 4 squares
- Reinforcing sterile dressings
- Tincture of benzoin
- Adhesive tape
- Sterile gloves and gown
- Face mask with an eye shield or goggles and cap

The supplies for an occlusive dressing (i.e., petrolatum gauze) may not be readily available within or outside of the Emergency Department. Numerous substitutes for the petrolatum gauze are available. This includes a defibrillator pad. These gel-like pads are large, can be cut to size, and adhere to both dry and wet skin. Other alternatives include coating water-soluble lubricant onto one side of a piece of aluminum foil, plastic food wrap, a piece cut from the plastic packaging of sterile procedure packs, a piece cut from a plastic trash bag, or a piece cut from a zippered sandwich bag.

There are commercially available open chest wound seals.¹⁶ The Hyfin Vent Chest Seal (North American Rescue LLC, Greer, SC) allows one-way airflow out of the chest cavity during exhalation (Figure 53-3A). It is clear to allow visualization of the underlying wound, is latex free, and is peel-and-apply. The SAM Chest Seal (SAM Medical Products, Wilsonville, OR) has a dual-vent

technology that enables simultaneous air and blood release from the chest cavity (Figure 53-3B). This transparent dressing has a channel design that minimizes vent occlusion and the need to manually vent the chest wound. It also has a cap allowing it to be used as an occlusive dressing. The domed shape was designed to prevent obstruction of the air channels from blankets and clothing. The Sentinel Chest Seal (Combat Medical Systems, Harrisburg, NC) is also transparent, allows venting of air and blood, and is designed to minimize vent occlusion (Figure 53-3C). The FastBreathe Thoracic Seal (FastTrack Medical Solutions LLC, Eden Prairie, MN) is a transparent, hardened, one-way valve assembly that has a low profile (Figure 53-3D). It allows air to be expelled with minimal intrathoracic pressure. The PractiSeal (S.T.A.T., San Luis Obispo, CA) is a training chest seal that is cost effective and not for use in patients (Figure 53-3E).

PATIENT PREPARATION

The amount and timing of patient preparation will be dictated by the location of the patient and their physiologic status. An informed consent is not required, as this is a noninvasive and lifesaving procedure. Such procedures should occur emergently with minimal patient preparation. If time permits, place the patient on the cardiac monitor and pulse oximeter, and provide supplemental oxygen by face mask. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids.

Consider performing orotracheal intubation before or simultaneously with the application of the three-sided occlusive dressing if the patient has severe respiratory insufficiency. Positive-pressure ventilation through the endotracheal tube will expand the collapsed lung and force the intrapleural air out the wound and into the atmosphere.

Prepare the chest wall if the patient is asymptomatic, mildly symptomatic, or moderately symptomatic. Clean the wound and surrounding chest wall of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin surrounding the wound and allow it to dry. Do not place the povidone iodine or chlorhexidine into the wound, as this may later inhibit wound healing. Apply the three-sided occlusive bandage as described below. **If the patient is moderately to severely symptomatic, no preparation is required as this wastes valuable time. Immediately apply the three-sided occlusive bandage.**

TECHNIQUE

The safest initial therapy for symptomatic sucking chest wounds is the careful application of a petrolatum gauze-based dressing taped on three sides (Figure 53-4). Apply three or four layers of petrolatum gauze over the wound. The dressing should extend 6 to 8 cm beyond the margins of the wound so that it will not be sucked into the pleural cavity in the spontaneously breathing patient. Cover the petrolatum gauze with dry 4 × 4 gauze squares. Apply tincture of benzoin around three sides of the dressing. Apply tape to secure the three sides of the dressing to the chest wall.

ALTERNATIVE TECHNIQUES

An alternative to the three-sided dressing is one that is totally occlusive or a four-sided dressing.^{15,17} There is little to no clinical evidence that a three-sided dressing is superior to a four-sided dressing. **The four-sided dressing should be placed only in the setting where rapid placement of a chest tube will be undertaken.** This occurs most commonly in the Emergency Department. It may be considered in the field when a tube thoracostomy is included in the pre-hospital standing medical orders.¹⁸

FIGURE 53-4. The three-sided occlusive dressing.

ASSESSMENT

Once the three-sided dressing has been placed, continue to closely monitor the patient for associated complications and evaluate them for underlying injuries. **Paramount among the complications is conversion of a simple pneumothorax to a tension pneumothorax. Do not be led into a false sense of security after placing the three-sided dressing. A patient can still develop a tension pneumothorax.** Periodically evaluate the three-sided dressing to ensure that it is not covered with another dressing or blankets, that it is not positioned between the patient and the bed or another object, and that it has not become occluded on all four sides. **If a tension pneumothorax occurs, remove the occlusive dressing on at least one side or perform a needle thoracostomy (Chapter 50) to relieve it.** Patients with an open chest wound have typically sustained an injury comprising great kinetic energy, whether from a blunt or penetrating event. Associated injuries will be very common. A head-to-toe secondary survey is imperative.

AFTERCARE

The aftercare of these patients consists of a tube thoracostomy followed by aggressive wound care, pain management, pulmonary toilet, continued monitoring, and investigation for other underlying injuries. **Once the wound is closed, the underlying pneumothorax or hemopneumothorax should be treated with the placement of a chest tube placed through an incision away from the injury site and not through the open chest wound.**

Pain will be a major problem for these patients. Trauma to the parietal pleura, bony structures, and intercostal nerves is very painful. It is imperative that these patients be able to make adequate ventilatory efforts, cough, deep breathe, perform incentive spirometry, and have aggressive pulmonary toilet. These are all necessary to prevent atelectasis, retained secretions, and pneumonia.¹⁹ Various pain-relieving techniques may be used. Infiltration of long-acting local anesthetic solution may give initial relief, especially during wound debridement. Parenteral analgesics are the initial treatment modality. Advanced techniques to consider include regional nerve blocks (i.e., intercostal nerve blocks) and indwelling intrapleural or epidural catheters.

More definitive wound care should be considered once the patient is stabilized. Small, clean wounds may be managed simply

with routine wound care and changes of the occlusive dressing. Local irrigation and debridement may be added if there is a limited amount of contamination. Large, grossly contaminated, and/or complex wounds are best managed in the Operating Room. Optimally, these wounds should be debrided and closed primarily. However, some wounds may be contaminated or complex, such that closure is not possible initially. In such cases, the wound should be debrided and left open. Large occlusive dressings are placed along with chest tubes for removal of air, fluid, and blood. Multiple operative debridements may be required. When the wound is clean and the patient is optimized, secondary closure may be performed.¹⁹

Closure of large wounds may require a combination of complex techniques. These may include various skin, subcutaneous tissue, and muscle flaps.²⁰ Free rib grafts, pectoral muscle flaps, latissimus dorsi muscle flaps, abdominal muscle flaps, omentum flaps, skin grafts, or a myocutaneous flap can be used.²⁰⁻²⁷ If using these is not possible, closure may be accomplished with a prosthetic material such as Prolene or Marlex, either temporarily or definitively.²⁸⁻³⁰ In wounds of the lower chest, detachment of the diaphragm with reattachment at a higher level may be used. This converts an open chest wound to an intraabdominal wound and alleviates the ventilatory problems.

COMPLICATIONS

Complications may occur acutely or may be delayed. **Occlusion of the chest wall defect and decompensation of the patient from a simple pneumothorax being converted to a tension pneumothorax are the primary early complications.**¹⁵ **The patient must be closely monitored until a chest tube can be inserted.** A tension pneumothorax can result if the wound is completely occluded by a blood clot, a dressing that has been sucked into the wound, soft tissue, or a bandage that is adherent on all four sides. **Immediately remove the bandage to relieve a tension pneumothorax.** Some physicians and authors remove only one side of the occlusive bandage to relieve the pneumothorax. The choice to remove part or all of the bandage is physician-dependent. Ensure that the wound is not occluded by a blood clot or soft tissue if the patient is still symptomatic after removing part or all of the bandage.

Other complications can ensue from the failure to seek, diagnose, and treat other underlying and potentially life-threatening injuries. The patient may develop respiratory insufficiency secondary to multiple causes, some of which may be preventable with optimal care. These causes include inadequate pulmonary toilet, inadequate pain management, pulmonary contusion, pneumonia, and/or adult respiratory distress syndrome. Wound complications may include infection, fasciitis, osteomyelitis, empyema, hemothorax, and loculated hemothoraces or pneumothoraces. These wounds require frequent evaluation and aggressive care to prevent these sequelae.

SUMMARY

Open chest wounds are easily diagnosed by the evident chest wall defect and the auscultation of air moving into and out of the pleural cavity. This is a true life-threatening emergency. Treatment is dictated by the patient's clinical presentation. Lifesaving therapy should be undertaken with the simple application of a three-sided petrolatum gauze dressing. The three-sided dressing allows air within the pleural cavity to be expelled into the atmosphere while preventing atmospheric air from entering the pleural cavity. The three-sided dressing converts the open pneumothorax to a closed pneumothorax and eliminates the major physiologic derangement. Once the patient is stabilized, more definitive care should be carried out with chest tube placement and appropriate wound care.

Emergency Department Thoracotomy

Kenny Banh

INTRODUCTION

An increase in urban violence combined with better prehospital and transport systems has resulted in the arrival of sicker trauma patients to the Emergency Department (ED). Previously, these patients might not have survived long enough to make it to the ED.¹ The majority of individuals with penetrating chest injuries arrive at the ED in stable condition and are managed without major operative procedures.² A subset of individuals, however, arrive in extremis and may require a thoracotomy. The purpose of the ED thoracotomy may be to control hemorrhage within the chest or below, to relieve a pericardial tamponade, to redistribute cardiac output to the brain and the heart, or to provide more effective cardiac massage.³

ANATOMY AND PATHOPHYSIOLOGY

The structures within the chest include the heart, esophagus, lungs, bronchi, pulmonary hilar vessels, and numerous other vascular structures. The heart is located in the anterior mediastinum. The aorta and esophagus are located in the posterior mediastinum. The internal mammary arteries course along the posterior aspect of the anterior chest wall just lateral to the sternum. The intercostal vessels run along the inferior aspect of the ribs. The subclavian vessels are at the very superior aspect of the thorax. They course directly under the clavicles and can be very difficult to visualize via an anterolateral thoracotomy. The azygos vein can be found coursing along the posterior right hemithorax and empties into the superior vena cava.

The heart is covered by the tough pericardial sac. **The phrenic nerves run superiorly and inferiorly on each side of the pericardial sac.** They can be visualized as white or yellow strands on either side of the pericardium. Once the pericardial sac is opened, the left anterior descending coronary artery can be visualized on the anterior surface of the heart. It overlies the interventricular septum. Injuries to the left of this artery usually denote left ventricular damage, whereas injuries to the right usually denote right ventricular damage. The majority of the anterior surface of the heart is occupied by the right ventricle.

The posterior mediastinum contains the aorta. It is located posterior to the esophagus and runs lateral to the vertebral bodies. The thoracic aorta gives off the intercostal vessels. If torn during the mobilization of the aorta, the intercostal vessels can cause troublesome bleeding.

The ED thoracotomy was originally introduced for penetrating chest wounds.⁴ This procedure was subsequently used for patients with penetrating abdominal wounds and victims of blunt trauma. **In recent years, several studies have shown an abysmal survival rate associated with an ED thoracotomy in victims of blunt trauma, including children.**^{5,6} When vital signs are present in the field, the survival rates for such individuals range from 0.6% to 6.0%.⁷⁻¹² Patients who undergo an ED thoracotomy for penetrating abdominal injuries have survival rates of approximately 5%.^{11,13} In these cases, the ED thoracotomy is performed for resuscitation purposes.

Blunt trauma arrests are difficult to resuscitate and not agreed upon by expert Surgeons.¹⁴⁻¹⁶ The Western Trauma Association recommends a thoracotomy for adults with blunt cardiac arrest if there are any signs of life or < 10 minutes of cardiopulmonary resuscitation (CPR).¹⁴ Advanced trauma life support does not recommend resuscitation of these patients. A systematic review showed up to a

1.5% overall survival rate with a good neurologic outcome.¹⁶ It also showed survival to be essentially zero if the patient has no signs of life in the field. The review conclusions were that thoracotomy may be useful in patients with vital signs in the ED, 15 minutes of CPR, and no head injury.

Patients presenting to the ED with penetrating chest trauma who present without signs of life in the field have a poor prognosis. Survival ranges from 0% to 9%.^{17,18} If the patient sustains penetrating chest trauma and has signs of life in the field, survival averages 14%, with a range of 0% to 36%.¹ The reason for the wide range probably lies in the small numbers of patients in the studies and the varying definitions of “signs of life.”

The best survival for penetrating chest injury and an ED thoracotomy is in patients with stab wounds resulting in cardiac tamponade. The use of bedside ED ultrasonography allows better identification of these patients.¹⁹ The survival for this entity ranges from 21% to 71%, averaging 31%.^{10,12,20-25} It should be noted that up to 90% of patients who survive an ED thoracotomy for penetrating chest injuries have good neurologic outcomes.²⁴⁻²⁷ This must be contrasted with a 50% incidence of a good neurologic outcome in the few survivors of blunt trauma who receive a thoracotomy.²⁸

INDICATIONS

There is little consensus among trauma surgeons on the exact indications of an ED thoracotomy.²⁹⁻³¹ **Signs of life present at the scene, signs of life at any time during the transport, or a resuscitation with a short transport time should prompt an ED thoracotomy in patients with penetrating chest trauma.**^{20-23,32,33} These signs include a palpable pulse, a blood pressure, pupil reactivity, any purposeful movement, an organized cardiac rhythm, or any respiratory effort. **Thus, the patient must have signs of life on presentation or have lost them en route to the ED if a thoracotomy is to be considered.** A thoracotomy should be performed to control hemorrhage within the thoracic cavity, to decompress a pericardial tamponade, to cross-clamp the aorta and redistribute the cardiac output to the brain and heart, and to provide open cardiac massage.³⁴ Patients who are in shock or rapidly deteriorating clinically after penetrating chest trauma and are not responding to aggressive fluid resuscitation are also candidates for an ED thoracotomy. It is also indicated to cross-clamp the aorta when the patient is exsanguinating from injuries below the level of the diaphragm.^{33,35} Consider a thoracotomy if the patient has a pericardial tamponade not relieved with a pericardiocentesis and cardiac arrest.^{36,37} A final indication is the placement of a chest tube (Chapter 51) with > 1500 mL of immediate blood return or a persistent bleed of 150 to 200 mL/h for 2 to 4 hours.³⁸

CONTRAINDICATIONS

There are a few well-supported contraindications to performing an ED thoracotomy. **A thoracotomy should not be performed in trauma patients who have no vital signs in the field.**^{15,39,40} In the absence of field vitals, the survival rates are extremely low and the few who survive have severe neurologic impairment. **Outside of patients who collapse in the ED, victims of blunt trauma with or without field vitals should not routinely undergo an ED thoracotomy.**^{40,41} It is also contraindicated when prehospital CPR exceeds 10 minutes without a return of spontaneous circulation after blunt trauma, when prehospital CPR exceeds 15 minutes without a return of spontaneous circulation after penetrating trauma, and when the patient presents to the ED in asystole without a pericardial tamponade.³⁹⁻⁴³ **An ED thoracotomy should not be performed regardless of the indications if a Trauma Surgeon or other qualified Surgeon is not available to take the patient to the Operating Room for definitive management.**

Do not perform an ED thoracotomy with the anticipation of transferring the patient to another facility if they can be resuscitated. In the near future, resuscitative endovascular balloon occlusion of the aorta (REBOA) may make some indications for a thoracotomy into contra-indications (Chapter 74).

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile towels
- Sterile gloves and gown
- Face mask with an eye shield or goggles and cap
- Sandbags or towels
- #3 scalpel handle
- #10 scalpel blade
- U.S. Army retractors, 1 set
- Curved Mayo scissors, 8¾ and 6¾ inches
- Curved Metzenbaum scissors, 5½ inches
- Toothed forceps
- Satinsky vascular clamp
- Finochietto rib retractor, 12 inch spread
- Suction source
- Suction tubing
- Yankauer suction catheter
- 2–0 silk suture on a large curved needle
- Hemostats needle driver, 10 inches
- Gauze 4 × 4 squares
- Sternal saw, hand-operated
- Lebsche knife (sternal osteotome) and mallet

All hospital EDs should have prepackaged and sterile thoracotomy trays. Review the equipment available on the trays at your institution to become familiar with their contents before the tray is required emergently.

PATIENT PREPARATION

The patient should be fully monitored with a noninvasive blood pressure cuff, pulse oximetry, cardiac monitor, and end-tidal carbon dioxide monitor (if available). Explain the risks, benefits, and complications of the procedure to the patient and/or their representative. The patient is usually deteriorating and loses consciousness or is unconscious, and time is of the essence. This may limit obtaining an informed consent. Document the circumstances of not getting consent in the medical record.

The patient should already be supine, intubated, and ventilated. Abduct the left upper extremity 180° (Figure 54-1). The extremity should be held in position by an assistant or with the use of a soft restraint. Place sandbags or towels under the patient's left scapula. This will elevate the torso off the bed and allow for more complete access. Apply povidone iodine or chlorhexidine solution to the patient's left chest. Apply sterile drapes over the chest to demarcate a surgical field.

An ED thoracotomy is primarily performed on patients who are unresponsive. As such, there is no immediate need for analgesics, sedatives, or local anesthetic solution. If the patient is resuscitated, they will experience significant postprocedural pain. **Parenteral analgesics and sedatives should be available and administered if the patient survives and there are no contraindications.**

FIGURE 54-1. Patient positioning. Place a sandbag or towel under the left shoulder and abduct the left arm 180°. Identify the fifth intercostal space in the male (**A**) or the inframammary line in the female (**B**).

Set up the required equipment. Open the prepackaged, sterile thoracotomy tray on a bedside table. The tray should contain all the equipment required for the procedure. Sterile technique should be observed and followed by all involved personnel (i.e., cap, mask, sterile gown, and sterile gloves). This will protect the health care personnel from exposure to the patient's blood and body fluids as well as minimize the risk of infection if the patient survives.

TECHNIQUES

LEFT-SIDED THORACOTOMY

Apply the scalpel blade to the handle. Identify the site to be used to make the initial skin incision. This is the left fourth or fifth intercostal space, corresponding to the intercostal space below the nipple in a male and below the inframammary fold in a female (**Figure 54-1**). **Make an incision using one stroke of the scalpel and extending from the sternum to the posterior axillary line or the gurney (Figure 54-2A).** Carry the incision through the skin, subcutaneous tissues, and superficial chest musculature down to and through most of the intercostal muscles (**Figure 54-2A**). An Army retractor may be used to open and separate the edges of the incision but is not required.

Discontinue mechanical ventilation and advance the endotracheal tube into the right mainstem bronchus. This will allow the left lung to deflate and minimize injury upon entering the left thoracic cavity while still ventilating the right lung. As an alternative, briefly discontinue mechanical ventilation. Puncture through the intercostal muscles in the anterior axillary line with the curved Mayo scissors. Carefully extend the puncture 2 to 3 cm using the curved Mayo scissors. Insert the nondominant index and middle fingers through the incision and separate the lung from the chest wall. Advance the fingers and Mayo scissors simultaneously superiorly and then inferiorly to cut the intercostal muscles along the entire inner space (**Figure 54-2B**). Resume mechanical ventilation.

Insert the Finochietto retractor with the arm and crank positioned near the gurney (**Figure 54-2C**). Turn the crank to open the arms of the rib spreader. **Make sure that the lung is not caught between the arms of the rib spreader and the chest wall to avoid tearing the lung.** Clear any blood from the left hemithorax and inspect for any brisk bleeding. If extensive bleeding is observed, it must be controlled. Use digital pressure or hemostats to initially control intercostal artery or other bleeding vessels. Subsequently, place 2–0 silk

stitches to tie off the bleeding vessels. For subclavian vessels, digital control must be followed by rapid transport to the Operating Room, since these vessels are difficult to control through an anterolateral thoracotomy.

OPENING THE PERICARDIUM

Move the left lung superiorly and laterally to expose the pericardial sac. A pericardiectomy should be routinely performed if blood is seen within the pericardial sac, if the heart cannot be visualized through the pericardium, or if there is no other obvious injury within the chest and a potential cardiac injury may exist. Many Emergency Physicians and Trauma Surgeons will routinely open the pericardium when they are performing a thoracotomy, as a pericardial tamponade is difficult to detect visually and a potential cardiac injury may exist.

Open the pericardial sac anterior to the phrenic nerve. Grasp and elevate the pericardium with a toothed forceps anterior to the phrenic nerve, which appears as a white or yellow strand along the lateral aspect of the pericardium (**Figure 54-2D**). Make an incision in the pericardium near the apex of the heart using a curved Mayo scissors. On occasion, a patient with pericardial tamponade physiology will have a tense pericardium that can be grabbed with the forceps and a small incision will have to be made with the Mayo scissors or a scalpel blade facing upward. Normally a small amount of straw-colored fluid is expressed from the pericardium if no cardiac trauma has occurred. Carefully insert one of the jaws of the Mayo scissors into the pericardial sac. **Extend the incision with the Mayo scissors parallel to the phrenic nerve, from the apex of the heart to the root of the aorta.** Deliver the heart from the pericardium and inspect it for any injury (**Figure 54-2E**). Internal cardiac massage (Chapter 55) may be performed for asystole, bradycardia, and/or hypotension. Any cardiac wounds identified should be temporarily plugged (Chapter 56).

RIGHT-SIDED THORACOTOMY

If there is a high index of suspicion of injury in the right hemithorax with minimal or no injury found in the left hemithorax, the thoracotomy must be extended to the right side. Extend the incision through the sternum using a curved Mayo scissors and continue it to the right posterior axillary line (**Figure 54-3**). Remove the Finochietto rib spreaders from the left side and apply them to the patient's right fifth intercostal space. Examine the right hemithorax

FIGURE 54-2. ED thoracotomy. **A.** The initial incision is made through the skin, subcutaneous tissue, and superficial muscles. **B.** The intercostal muscles are incised with Mayo scissors. **C.** The Finochietto rib spreader has been inserted and opened. **D.** The pericardium is grasped and opened. **E.** A thoracotomy with the pericardium opened. (Part E used with permission from Cothren CC, Moore EE: Emergency department thoracotomy for the critically injured patient: objectives, indications, and outcomes. *World J Emerg Surg* 2006; 1:4.)

for injury. The internal mammary arteries on both sides will be lacerated when the sternum is cut. Apply hemostats to the transected vessels to obtain hemostasis. They may later be tied off if the patient is resuscitated.

Occasionally, the large curved Mayo scissors cannot transect the calcified sternum. Perform a right-sided thoracotomy similar to that on the left. If further access is required, cut the sternum with a hand-held sternal saw or Lebsche knife (**Figure 54-4**). Pass one end of the

FIGURE 54-3. The left-sided incision is continued across the sternum and the right fifth intercostal space to perform a right-sided thoracotomy.

sternal saw from the left fifth intercostal space, behind the sternum, and out of the right fifth intercostal space (**Figure 54-4A**). Place an index finger through the loop on each end of the sternal saw. Move the hands toward and away from the patient in a to-and-fro motion until the sternum is transected. Alternatively, a Lebsche knife can be used to transect the sternum. Place the hooked portion of the knife under the sternum with the sharp blade against the lateral border of the sternum (**Figure 54-4B**). Lift up the handle of the Lebsche knife to lock it against the posterior surface of the sternum. This will prevent the tip of the Lebsche knife from cutting the heart. Hit the flat knob on the back of the Lebsche knife with a mallet to drive the knife through the sternum (**Figure 54-4B**).

ASSESSMENT

Any bleeding should be controlled with the application of pressure, hemostats, and/or sutures. Any injuries to the heart (Chapter 56) or the hilum and great vessels (Chapter 57) should be managed. Cross-clamping of the proximal aorta will prevent further exsanguination from more distal injuries (Chapter 58). Open cardiac

massage can be performed while the resuscitative efforts continue (Chapter 55).

AFTERCARE

The patient should be immediately transported to the Operating Room for definitive care, as soon as the Anesthesiologist and Surgeon are available, if resuscitated in the ED. Continue the administration of fluids, packed red blood cells, platelets, plasma, and inotropic agents as necessary until the patient is hemodynamically stable. Administer broad-spectrum antibiotics intravenously if the patient is resuscitated and survives. Administer parenteral analgesics and/or sedation (Chapter 159) if not contraindicated.⁴⁴

COMPLICATIONS

The ED thoracotomy has many potential and serious complications. Fortunately, this procedure is often performed as a last effort for the resuscitation of a “dead patient.” The complications are, therefore, not significant when the alternative to this procedure is death.

The ED thoracotomy is rarely ever performed under truly sterile conditions. Time is often of the essence in performing this procedure. Povidone iodine or chlorhexidine solution and sterile drapes are rarely applied before an emergent ED thoracotomy. If applied, the povidone iodine or chlorhexidine solution does not have time to dry before the skin incision is made. The complications of the thoracotomy include vascular and organ injury. Lacerations of the internal mammary or intercostal arteries can be ligated with silk suture. There is also the possibility of inadvertent laceration of the lung or the myocardium during the initial incision. By temporarily halting mechanical ventilation while performing the thoracotomy, injury to the underlying lung can often be prevented. These injuries will need subsequent repair at the appropriate time.

A pericardiotomy can result in significant complications. The left phrenic nerve may be transected. The myocardium or a coronary artery can be lacerated. The heart may be fixed by adhesions to the pericardium from prior pericardial disease or pericarditis. Attempting to remove the heart from the pericardium can result in avulsion of the atrial or ventricular myocardium. Performance of the pericardiotomy adds another delay in initiating cardiac compressions.

FIGURE 54-4. Cutting the sternum. **A.** The sternal saw is moved to-and-fro while maintaining upward pressure. **B.** The Lebsche knife is hooked under the sternum and lifted upward to secure it in place. The mallet strikes the Lebsche knife and drives it through the sternum.

Care should be taken to prevent injury to any of the health care providers. Universal precautions should be followed by all personnel. The use of caps, gloves, goggles, masks, and gowns will protect against exposure to the patient's blood. All needles, scalpels, and scissors should be returned to the bedside tray immediately after use and not left on the patient or the bed. **Use extreme caution when placing your hands inside the patient's hemithorax.** Fractured ribs from the trauma or the Finochietto rib spreader can easily penetrate gloves and skin. The costs associated with an occupational exposure associated with an ED thoracotomy are quite significant, especially if the health care provider develops hepatitis C or HIV.^{5,42,45}

SUMMARY

An ED thoracotomy is a lifesaving procedure when used on select patients in extremis secondary to chest or abdominal trauma. To be considered for this procedure, the patient must have signs of life when brought to the ED, must have lost them en route, or must have lost them on the scene with a short transport time. This procedure should rarely be used in patients with blunt trauma. The Emergency Physician should have the appropriate surgical backup before performing a thoracotomy since this procedure does not provide definitive therapy. In the near future, REBOA may change some thoracotomy indications into contraindications.

Open Cardiac Massage

Eric F. Reichman

INTRODUCTION

The purpose of cardiopulmonary resuscitation (CPR) during cardiac arrest or hypovolemic shock is to provide adequate cardiac output. This can be done using either closed or open chest cardiac massage. Open cardiac massage may, on rare occasions, be performed in the Emergency Department. It is performed on patients who have had an emergent thoracotomy after penetrating chest trauma and have inadequate cardiac activity. It may also be performed, in rare instances, after a thoracotomy to decompress a pericardial tamponade in a medical patient. Open cardiac massage is considered a heroic procedure in the Emergency Department that can be lifesaving if performed on the appropriate patient.¹⁻¹²

Open cardiac massage was routinely performed before the introduction of closed chest CPR. This technique was primarily performed in hospitals by Surgeons. Most of the patients were surgical, and open cardiac massage had a high success rate. After the development of closed chest CPR in the early 1960s, there was a dramatic decline in open cardiac massage in the mid-to-late 1960s and 1970s. The exceptions were cardiac arrests due to trauma or in the Operating Room.

ANATOMY AND PATHOPHYSIOLOGY

The efficacy of cardiac massage can be established by measuring the cardiac output, coronary perfusion pressure, and cerebral perfusion pressure. A higher cardiac index can be achieved with open than with closed cardiac massage.¹ A minimal coronary perfusion pressure of 15 mmHg must be maintained for return of spontaneous circulation. While not all patients with this pressure will have a return of spontaneous circulation, a pressure of less than 15 mmHg predicts a uniformly fatal outcome.² While closed chest CPR generated only 1 to 9 mmHg of pressure, Boczar et al found that their patients all had a coronary perfusion pressure of almost 20 mmHg throughout open chest massage.³ Open chest CPR produces improved cerebral perfusion and better neurologic recovery.^{4,10} Open cardiac massage can generate near normal cerebral blood flow and improve cardiac perfusion pressure.

INDICATIONS

Open cardiac massage is indicated if absent or inadequate cardiac activity is noted after a thoracotomy for penetrating trauma, a thoracotomy to decompress a pericardial tamponade (spontaneous, postsurgical, or from an aortic dissection), or a cardiac arrest after recent chest surgery.^{7,9,11} Other possible indications include abnormal chest wall anatomy that prevents closed chest CPR, hypothermic cardiac arrest, refractory ventricular fibrillation, massive air embolism, and if standard CPR is not effective.

CONTRAINDICATIONS

The only absolute contraindication to performing open cardiac massage is the presence of a palpable pulse. Open cardiac massage is ineffective if the patient has a pericardial tamponade. Perform a thoracotomy and pericardiotomy to remove any clots from the pericardial sac. The heart may then begin to beat spontaneously. If not, repair any lacerations to the myocardium prior to performing cardiac compressions. Refer to Chapter 54 for a discussion in which a thoracotomy is contraindicated, as open cardiac massage is also

contraindicated. It is also contraindicated if the patient is clearly deceased.

EQUIPMENT

No equipment is required to perform open cardiac massage other than that needed to perform the thoracotomy and pericardiotomy (Chapter 54).

PATIENT PREPARATION

The preparation and positioning of the patient are exactly the same as those for a thoracotomy. A thoracotomy must first be performed (Figure 55-1). Refer to Chapter 54 for the complete details of a thoracotomy. A pericardiotomy should be performed only if absolutely necessary—that is, if blood is seen within the pericardial sac or cardiac tamponade is suspected. Remove any blood and clots from the pericardial sac, deliver the heart from the pericardial sac, and repair any myocardial lacerations (refer to Chapter 56).

An intact pericardium is preferable if open cardiac massage is to be performed. It prevents the fingertips from inadvertently rupturing the atria or ventricles should the heart be grasped incorrectly. The pressure from open cardiac massage is distributed over a larger area if the pericardium remains intact. The heart will move within the pericardial sac, which will prevent the fingers from compressing one spot for a prolonged time and may decrease the chance of myocardial rupture.

TECHNIQUES

Several important principles must be kept in mind prior to performing open cardiac massage. **The heart must be angled not more than 20° to 30° into the left hemithorax (Figure 55-2A).** Angulation of more than 30° may crimp the pulmonary veins and vena cava closed and thus minimize cardiac output. **The compressive forces should be applied perpendicular to the interventricular septum.** Place your hands directly behind and in front of the heart. The left anterior descending artery can be used as a landmark, as it runs above the interventricular septum. **Do not place the fingers over the coronary arteries so that their flow is occluded.** The fingertips should never be used to compress the heart, as they may rupture the myocardium. Use only the palm, volar surfaces of the fingers, and pads of the fingers to perform cardiac compressions. The fingers should always be held tightly together to form a flat surface. This allows the force of compression to be spread out and not concentrated over one finger. Each compression of the heart must be followed by complete relaxation of the heart. It is during this relaxation phase (diastole) that the cardiac chambers fill with blood and the coronary arteries perfuse the myocardium.

Three techniques have been described to perform open cardiac massage (Figures 55-2 and 55-3). These include one-handed massage with sternal compression, one-handed compression, and two-handed compression.¹² Two-handed compression has been shown to be consistently superior to the other two techniques in generating cardiac output.⁵

ONE-HANDED MESSAGE WITH STERNAL COMPRESSIONS

Tightly adduct the fingers of the dominant hand to make a flat surface. Insert the hand into the thoracotomy incision and against the posterior surface of the heart (Figures 55-2A and B). Angle the heart 20° to 30° into the left hemithorax. Compress the heart against the sternum, beginning with the heel of the hand, followed by the

FIGURE 55-1. The anterolateral thoracotomy.

FIGURE 55-2. One-handed open cardiac massage. **A.** The dominant hand angles the heart 20° to 30° into the left hemithorax. **B.** One-handed cardiac massage with sternal compression. **C.** The one-handed compression technique.

FIGURE 55-3. Two-handed open cardiac massage. **A.** The hands are positioned on the anterior and posterior surfaces of the heart. **B.** Compressions begin at the cardiac apex with the palms and progress toward the base of the heart with the fingers.

palm, and then followed by the fingers in sequence. This method is difficult to perform in children because of the plasticity of the sternum.⁶

ONE-HANDED COMPRESSIONS

Tightly adduct the fingers of the dominant hand to make a flat surface. Insert the hand into the thoracotomy incision and against the anterior surface of the heart (**Figure 55-2C**). Place the thumb against the posterior surface of the heart. The apex of the heart will lie in the palm of the hand (**Figure 55-2C**). Angle the heart 20° to 30° into the left hemithorax. Appose the thumb and fingers to compress the heart. This is not the preferred method, as the thumb can place significant pressure on the left ventricle and possibly cause it to rupture.

TWO-HANDED COMPRESSIONS

This is the technique of choice in children. The child's sternum, the costochondral tissues, and the ribs are mostly cartilage. This makes their sternum very pliable. This decreases effectiveness of the one-handed massage with sternal compression technique. The one-handed compression technique can rupture the thin myocardial walls.

Tightly adduct the fingers and cup the left hand. Insert the left hand into the thoracotomy incision and against the anterior surface of the heart (**Figure 55-3A**). Tightly adduct the fingers of the right hand to make a flat surface. Insert the right hand into the thoracotomy incision and against the posterior surface of the heart (**Figure 55-3A**). Angle the heart 20° to 30° into the left hemithorax. Appose both of the hands to compress the heart (**Figure 55-3B**). Compressions should ideally begin with the heel of the hands and progress toward the fingers.

ASSESSMENT

Compressions should begin at a rate appropriate for the patient's age as specified by the American Heart Association's Pediatric Advanced Life Support and Advanced Cardiac Life Support guidelines.^{13,14} Ideally, compress the heart at a rate of at least 100 times a minute if possible. This compression rate is based on consensus and not clinical research. Assess the effectiveness

of the cardiac compressions by noting a palpable carotid pulse. A radial or femoral arterial line can be placed to monitor the effectiveness of the compressions. The arterial line allows for repeated blood and blood gas sampling. The arterial line will also allow the Emergency Physician to ensure that the heart is completely relaxed between compressions.

AFTERCARE

If a spontaneous cardiac rhythm and a peripheral pulse return, cover the thoracotomy incision with a sterile saline-moistened gauze and a simple dressing. Administer intravenous antibiotics whose spectrum covers skin flora. The patient must be taken emergently to the Operating Room by a Trauma Surgeon or Cardiothoracic Surgeon for definitive treatment and closure of the chest wall.

COMPLICATIONS

The major complication of open cardiac massage is myocardial rupture or perforation. This can occur from compression of the heart against a jagged and fractured rib or sternum. Incorrect technique with too vigorous a massage can result in perforation of the ischemic myocardium by the fingertips. Other complications include decreased cardiac output with compressions if the heart is angled more than 30° into the left hemithorax and kinks shut the vena cava or pulmonary veins. Infection is possible if the patient survives. Parenteral antibiotics should be administered to prevent infection and sepsis. The complications associated with the thoracotomy and the pericardiotomy are discussed in Chapter 54. The quality of life of survivors can be poor to normal.⁸

SUMMARY

Open cardiac massage is a more efficient way of maintaining circulation than closed chest massage. Cardiac compressions can be performed with one or two hands, depending on physician preference. The two-handed technique is preferred, as it generates greater cardiac output than the one-handed techniques. Once a cardiac rhythm and blood pressure are restored, definitive treatment for injuries must be provided expeditiously by a Surgeon in the Operating Room.

Cardiac Wound Repair

Eric F. Reichman

INTRODUCTION

Wounds of the heart are highly lethal. Traumatic cardiac penetration carries a 70% to 80% fatality rate.¹ Major factors determining survivability include whether or not cardiac standstill has occurred as well as the amount of tissue destruction sustained from the injury.² A repair of a cardiac wound was first described in the literature in 1893.³

Penetrating wounds can be caused by knives, bullets, ice picks, and (infrequently) rib or sternal fragments. **Regardless of the offending agent, repair must be done as expeditiously as possible.** The right ventricle is the most frequently injured chamber.⁴ However, injury to the heart may occur at more than one site. This is especially true with gunshot wounds.¹

The treatment goal in the Emergency Department is temporary hemostasis. Many different techniques of cardiorrhaphy have been described. We will limit our discussion to five possible approaches to dealing with these injuries (i.e., digital or Foley catheter occlusion, vascular clamps, staples, and sutures).

ANATOMY AND PATHOPHYSIOLOGY

The heart is contained within the pericardial sac. Numerous portions of the heart are exposed behind the anterior chest wall (**Figure 48-2**). This includes the right ventricle, left ventricle, right atrium, left atrium, aorta, pulmonary artery, and inferior vena cava. These structures are vulnerable to injury behind the anterior chest wall.^{5,6} The surface areas that each of these structures contributes to the anterior cardiac silhouette are as follows: 55% right ventricle, 20% left ventricle, 10% right atrium, 10% aorta and pulmonary artery, 4% inferior vena cava, and 1% left atrium.⁷ These numbers also reflect, roughly, the anatomic incidence of injury with cardiac trauma.⁷ Traumatic injury to any of these structures can result in a pericardial effusion and cardiac tamponade. Injuries to more than one cardiac chamber can occur from a single gunshot or stab wound.^{4,8} Cardiac wall injuries can also occur following blunt trauma.⁹

INDICATIONS

Any penetrating injury to the heart requires immediate and temporary repair to prevent the patient from exsanguinating. A bluish hue behind the pericardium or a tense pericardial sac after penetrating trauma suggests an underlying cardiac injury. A pericardiotomy should be performed, any blood and clot removed from the pericardial sac, and the heart explored for the site of injury. The indications to perform a thoracotomy are described in Chapter 54.

CONTRAINDICATIONS

The only absolute contraindication to performing a cardiorrhaphy is if the patient has obvious signs of death. It should not be performed if the patient has not had any vital signs for over 15 minutes, as anoxic brain injury is irreversible. It is also contraindicated in patients with penetrating chest trauma who do not meet the criteria for performing an anterolateral thoracotomy. Refer to Chapter 54 for a discussion in which a thoracotomy is contraindicated, as any cardiac repair is also contraindicated. There is a less than 1% chance of survival if the patient has multiple gunshot wounds to the torso.^{10,11} It is up to the discretion of the treating physician in cases of multiple gunshot wounds to the torso if a thoracotomy is to be done due to the generally accepted unsalvageability.^{10,11}

EQUIPMENT

- Sterile gloves and gown
- Face mask with an eye shield or goggles and cap
- Silk suture, 4-0 and 5-0 (or Prolene)
- 2-0 silk, on a semicircular atraumatic needle
- 10 inch needle driver
- Foley catheter, sizes 14 to 20 French
- Satinsky, or other, atraumatic vascular clamp (**Figure 56-1**)
- Allis clamps
- Defibrillator with internal cardiac paddles
- Mayo scissors
- Metzenbaum scissors, curved
- Teflon pledgets
- Sterile saline
- 20 mL syringe

FIGURE 56-1. Examples of several atraumatic vascular clamps.

- Standard skin stapler, 6 mm wide staples
- Laparotomy pads
- Gauze 4 × 4 squares
- Hemostats

PATIENT PREPARATION

No preparation is required other than that of performing a thoracotomy and a pericardiotomy (Chapter 54). The patient should be intubated, ventilated with 100% oxygen, and fully monitored (i.e., telemetry, a noninvasive blood pressure cuff, and pulse oximetry). Instruct a nurse to administer intravenous broad-spectrum antibiotics that cover skin flora, gram-positive organisms, and gram-negative organisms. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. Although time is of the essence and this is an emergent procedure, aseptic technique should be followed. A thoracotomy must first be performed. Refer to Chapter 54 for the complete details of a thoracotomy.

TECHNIQUES

Bleeding from a cardiac wound should ideally be stopped by placing a finger over the wound and immediately transporting the patient to the Operating Room for definitive repair. Unfortunately, the Anesthesiologist, Surgeon, and/or Operating Room may not be immediately available. If the Emergency Physician performs a thoracotomy, they should be versed in methods of temporary cardiac wound repair. Several techniques are available to control hemorrhage from a cardiac wound.¹²

CONTROL OF THE HEART

It is extremely difficult to maintain a finger over a cardiac wound or to stitch a cardiac wound if the heart is beating. An apical traction suture known as Beck's suture can be placed to control the heart (**Figure 56-2**). The apex of the heart is the ideal site because it is often away from most lacerations, is a thick portion of the heart, and is away from any major coronary arteries. Place a 2-0 silk suture through the apex of the heart and remove the needle from the suture. The ends of the suture can be grasped by hand or with a hemostat to elevate and control the heart while it is beating.

FIGURE 56-2. The apical traction suture known as Beck's suture may be placed to control the heart.

SAUERBRUCH MANEUVER

Large cardiac wounds and wounds with significant bleeding are difficult to repair, as the blood obscures the surgical field. Experienced Surgeons may temporarily clamp the inferior and superior vena cava to maintain a bloodless field. **Clamping the vena cava should not be performed by an Emergency Physician, as it is time-consuming and can injure other structures.** A quicker and safer alternative is the Sauerbruch maneuver, or grip, to partially occlude venous inflow through the inferior and superior vena cava (**Figure 56-3**). This technique will stabilize the heart for wound repair and allow the bleeding site to be identified and repaired.

Insert the nondominant hand into the pericardial cavity and toward the vena cava. Place the middle finger behind the vena cava and the index finger in front of the vena cava (**Figure 56-3**). The thumb should be resting on the anterior surface of the heart. The ring and little fingers should be resting on the posterior surface of the heart. Use the thumb and the ring and little fingers to cradle the heart while apposing the middle and index fingers to partially occlude the vena cava. This technique can be used to control hemorrhage from the heart, great vessels, or hilum. **While effective at controlling hemorrhage, this technique will significantly reduce cardiac output and may result in cardiac arrest. The grip should be released every 30 to 60 seconds to ensure coronary artery perfusion.**

DIGITAL OCCLUSION

Digital occlusion of small cardiac wounds can provide excellent hemostasis while awaiting definitive repair. Once a finger is placed on or over the defect, it must remain there until the appropriate materials to perform cardiorrhaphy are available. **Do not place a finger into the defect as this may increase the size of the wound.** Unfortunately, the fingertip often slips off the wound

FIGURE 56-3. The Sauerbruch maneuver to partially occlude venous inflow from the superior and inferior vena cava.

if the heart is beating. The fingertip interferes with visualization and repair of the wound. It also places the Emergency Physician at risk for a needle-stick injury while attempting to repair the wound.

FOLEY CATHETER TECHNIQUE

A Foley catheter may be used to provide temporary hemostasis (**Figure 56-4**). As with digital occlusion, this is only a temporizing measure. Inflate the cuff of the Foley catheter with sterile saline to check its integrity and look for leaks. **Deflate the cuff. Place a hemostat on the Foley catheter 3 to 4 cm proximal to the cuff. This will prevent air from being drawn through the catheter and causing an air embolism.**

Identify the location of the cardiac wound (**Figure 56-4A**). Insert the Foley catheter through the cardiac wound until the balloon is within the cardiac chamber (**Figure 56-4B**). Release the hemostat, inflate the cuff with 10 to 20 mL of sterile saline, and reclamp the Foley catheter (**Figure 56-4C**). **This step should be done quickly to prevent air from being drawn through the Foley catheter and into the heart.**

Apply gentle traction to the catheter (**Figure 56-4D**). Apply just enough traction to mostly occlude the wound and slow the bleeding. A small amount of bleeding is adequate and acceptable to visualize the wound and perform a temporary repair. Do not try to provide complete hemostasis. Providing complete hemostasis can result in excessive traction on the Foley catheter causing the cuff to pull through the wound, enlarge the wound, and further lacerate the myocardium.

Repair the cardiac wound. Place a purse-string suture around the wound (**Figure 56-4E**). Use caution when placing the suture

FIGURE 56-4. The Foley catheter technique to occlude and repair a cardiac wound. **A.** The cardiac wound is identified. **B.** The Foley catheter is inserted through the wound. **C.** The cuff is inflated. **D.** Gentle traction is applied to occlude the wound with the cuff. **E.** A purse-string suture is placed around the wound. **F.** The cuff is deflated, and the Foley catheter is removed. **G.** The purse-string suture is tightened and tied to occlude the wound.

so that the needle does not pierce and rupture the cuff of the Foley catheter. The Foley catheter may be advanced into the cardiac chamber temporarily while the suture is being placed. This will prevent the needle from piercing the cuff. **Do not advance the cuff too far into the heart and for too long a time period. The cuff may occlude blood flow through the valves and result in cardiac arrest.** After the purse-string suture is placed, deflate the cuff and quickly remove the Foley catheter (Figure 56-4F). Tie the ends of the suture to close the cardiac wound (Figure 56-4G). Place additional knots to secure the suture.

The Foley catheter technique is simple and effective. It avoids the problems associated with digital occlusion. The catheter may be placed in posterior cardiac wounds that are difficult to visualize and where it is hard to maintain digital occlusion. The Foley catheter does not interfere with visualization of the wound, wound repair, or the simultaneous performance of cardiac massage. Intravenous catheter tubing may be inserted into the lumen of the Foley catheter to infuse crystalloid solutions or red blood cells directly into the heart and central circulation. This technique is especially valuable in repairing wounds at the junction of the right atrium and vena cava.

CLAMP TECHNIQUE

Atrial wounds can bleed profusely and are difficult to control. The thin walls do not allow digital occlusion to be effective. The atrial wound can be grasped and compressed between the thumb and index finger. An atraumatic Satinsky vascular clamp, or other atraumatic vascular clamp (Figure 56-1) in the thoracotomy tray, can be placed around the wound to provide hemostasis (Figure 56-5). The wound may then be repaired with 4-0 or 5-0 interrupted silk sutures.

Allis clamps may be substituted if an atraumatic vascular clamp is not available. Place an Allis clamp on each of the opposing edges of the atrial wound. Apply upward traction and then cross the Allis clamps to approximate the wound edges. The wound may now be sutured closed. The Allis clamps do not provide as bloodless a field as does the atraumatic vascular clamp.

FIGURE 56-5. A Satinsky vascular clamp provides hemostasis for atrial wounds.

STAPLE TECHNIQUE

Skin staplers provide a quick and easy method to repair cardiac wounds. Careful approximation and stapling of the wound will rapidly close the defect and aid in controlling massive blood loss. Staples may be used to close small, large, or multiple lacerations. Its use avoids the potential complication of a needle stick to the Emergency Physician.

Cardiac wounds are closed similarly to skin lacerations (Figure 56-6). Obtain a standard skin stapler with 6 mm wide staples. These are readily available in most Emergency Departments for wound closure. Use the nondominant hand to appose the wound edges. Grasp the stapler with the dominant hand. Place staples at 5 mm intervals until the wound is closed. **Avoid any visible epicardial coronary vessels or use an alternate technique. Closing or damage to the vessels can result in myocardial ischemia, myocardial infarcts, and cardiac arrest.**

SUTURE TECHNIQUES

Suturing of cardiac wounds is more time consuming than the other methods previously described. It requires technical proficiency and understanding of the heart's surface anatomy. Place horizontal mattress sutures using 2-0 or 3-0 silk or Prolene suture material (Figure 56-7). **Do not tie the sutures tightly. It is easy to inadvertently tear through the myocardium.** Use Teflon pledgets to reinforce the repair and prevent cutting through the heart tissue (Figures 56-7A and B). This is especially important when the wound edges are irregular or tattered. Use care to avoid injury to the coronary vessels, which may lie in close proximity to a cardiac wound. Ensure that the sutures are placed adjacent to and underneath the coronary vessels (Figure 56-7C).

Large cardiac wounds are difficult to repair. They bleed profusely. The digital occlusion and Foley catheter techniques are ineffective on large wounds. The wound edges are difficult to grasp and appose so that they can be repaired with a skin stapler. Place an incomplete horizontal mattress stitch on each side of the wound (Figure 56-8). Grasp the free ends of the sutures and cross them across the wound to appose the wound edges. Instruct an assistant to hold the suture ends while the cardiac wound is repaired

FIGURE 56-6. The cardiac stapling technique provides temporary hemostasis.

FIGURE 56-7. Horizontal mattress sutures used to close cardiac wounds. **A.** Teflon pledgets are placed on either side of the wound to prevent the suture from pulling through the myocardium. **B.** Wounds are closed with multiple horizontal mattress sutures. **C.** When suturing near a coronary artery, ensure that the sutures pass completely below the artery.

FIGURE 56-8. Incomplete horizontal mattress stitches may be placed on each side of a large wound. Tension applied to the sutures will appose the wound edges (arrows).

FIGURE 56-9. The internal cardiac paddles inserted into the handles.

with 2-0 or 3-0 silk, Prolene, or staples. The incomplete mattress sutures may then be removed or tied to each other.

FIBRILLATION

The myocardium can be deliberately placed in fibrillation to halt myocardial contractions and repair large ventricular wounds. **This should be performed only if other techniques of cardiac wound repair are unsuccessful.** Choose the proper size internal cardiac paddles. The paddle size is 2 cm for an infant, 4 cm for a child, and 6 cm for an adolescent or adult. Insert the sterile paddles into the sterile handles (**Figure 56-9**). Pass the cables exiting the base of the

handles to an assistant to insert into the defibrillator machine ports. Instruct the assistant to turn on the defibrillator.

Place the internal cardiac paddles on the anterior and posterior surfaces of the heart (**Figure 56-10**). While the paddles can be placed directly on the heart, it is recommended by some to place sterile saline-moistened gauze squares between the paddles and the heart to aid in conduction. Apply 20 Joules (J) of energy through the paddles to fibrillate the adolescent or adult heart. Begin with 5 J of energy to fibrillate the infant or child heart. Proceed upward incrementally as required to a maximum of 20 J to fibrillate the infant or child heart.

Quickly repair the cardiac wound.

Perform intermittent open cardiac massage (Chapter 55) while repairing the fibrillating myocardium to maintain cardiac output. Do not allow the heart to fibrillate for more than 3 minutes. Defibrillate the heart with the internal paddles using 20 J of energy for the adult and adolescent heart. Repeat the defibrillation with 20 J of energy until the heart begins beating. **In general, do not use more than 20 J to defibrillate the adult or adolescent heart with the internal cardiac paddles as myocardial necrosis can occur.** It may be occasionally necessary to increase the energy in the adolescent or adult to 40 J then 60 J if multiple attempts at 20 J are ineffective. Begin with 5 J of energy to defibrillate the infant or child heart. Proceed upward incrementally as required to a maximum of 20 J to defibrillate the infant or child heart.

ALTERNATIVE TECHNIQUES

There are several alternative techniques for cardiac wound repair.¹³⁻¹⁵ They cannot be recommended for use in the Emergency Department at this time due to lack of information. They may be adopted in the future with some modification. Pericardial drainage for tamponade may stabilize the patient long enough to get them to the Operating Room for surgical repair.¹³ BioGlue (CryoLite Inc.,

A

B

FIGURE 56-10. Application of the internal cardiac paddles. **A.** Sterile saline-moistened gauze can be placed between the paddles and the heart to increase conductivity. **B.** The paddles are properly positioned in a patient. (Used with permission from Cothren CC, Moore EE: Emergency department thoracotomy for the critically injured patient: objectives, indications, and outcomes. *World J Emerg Surg* 2006; 1:4.)

Kennesaw, GA) has been used to repair penetrating cardiac wounds successfully in the Operating Room.¹⁴ This BioGlue is made of synthetic bovine albumin and glutaraldehyde. The Wyss Institute at Harvard University developed a specialized catheter to fix holes in the heart.¹⁵ It uses a biodegradable adhesive and patch with ultraviolet light to patch the beating heart.

A new device has recently been developed.¹⁶ It consists of a flexible plastic shaft (approximately 3 mm in diameter and 12 cm long), 4 cm diameter silicone suction cup, and a circular low-profile collapsible blood flow blocking membrane (Figure 56-11A). The suction cup is adjustable to different positions along the shaft. The collapsible membrane is made of natural rubber and is 3.5 cm in diameter and 1 mm in width. The collapsible blood flow blocking membrane is inserted through the cardiac injury (Figure 56-11B). The silicone suction cup is then moved down to the surface of the heart to abut the ventricle wall, creating a firm seal (Figures 56-11C and D). The device is removed by the Surgeon by sliding the suction cup along the plastic shaft and away from the surface of the ventricle and then

pulling the device out of the wound. This device is not yet available commercially but will make cardiac wounds easier to manage in the Emergency Department.

AFTERCARE

If the patient is resuscitated, cover the thoracotomy wound with saline-moistened gauze and a simple dressing. Administer broad-spectrum antibiotics if not done previously. Immediately transport the patient to the Operating Room for definitive repair of the cardiac wound and any other injuries by a Trauma or Cardiovascular Surgeon.

COMPLICATIONS

The complications associated with digital pressure include further destruction of tissue. Foley catheters can become dislodged and restart troublesome bleeding if pulled too tightly. They can also

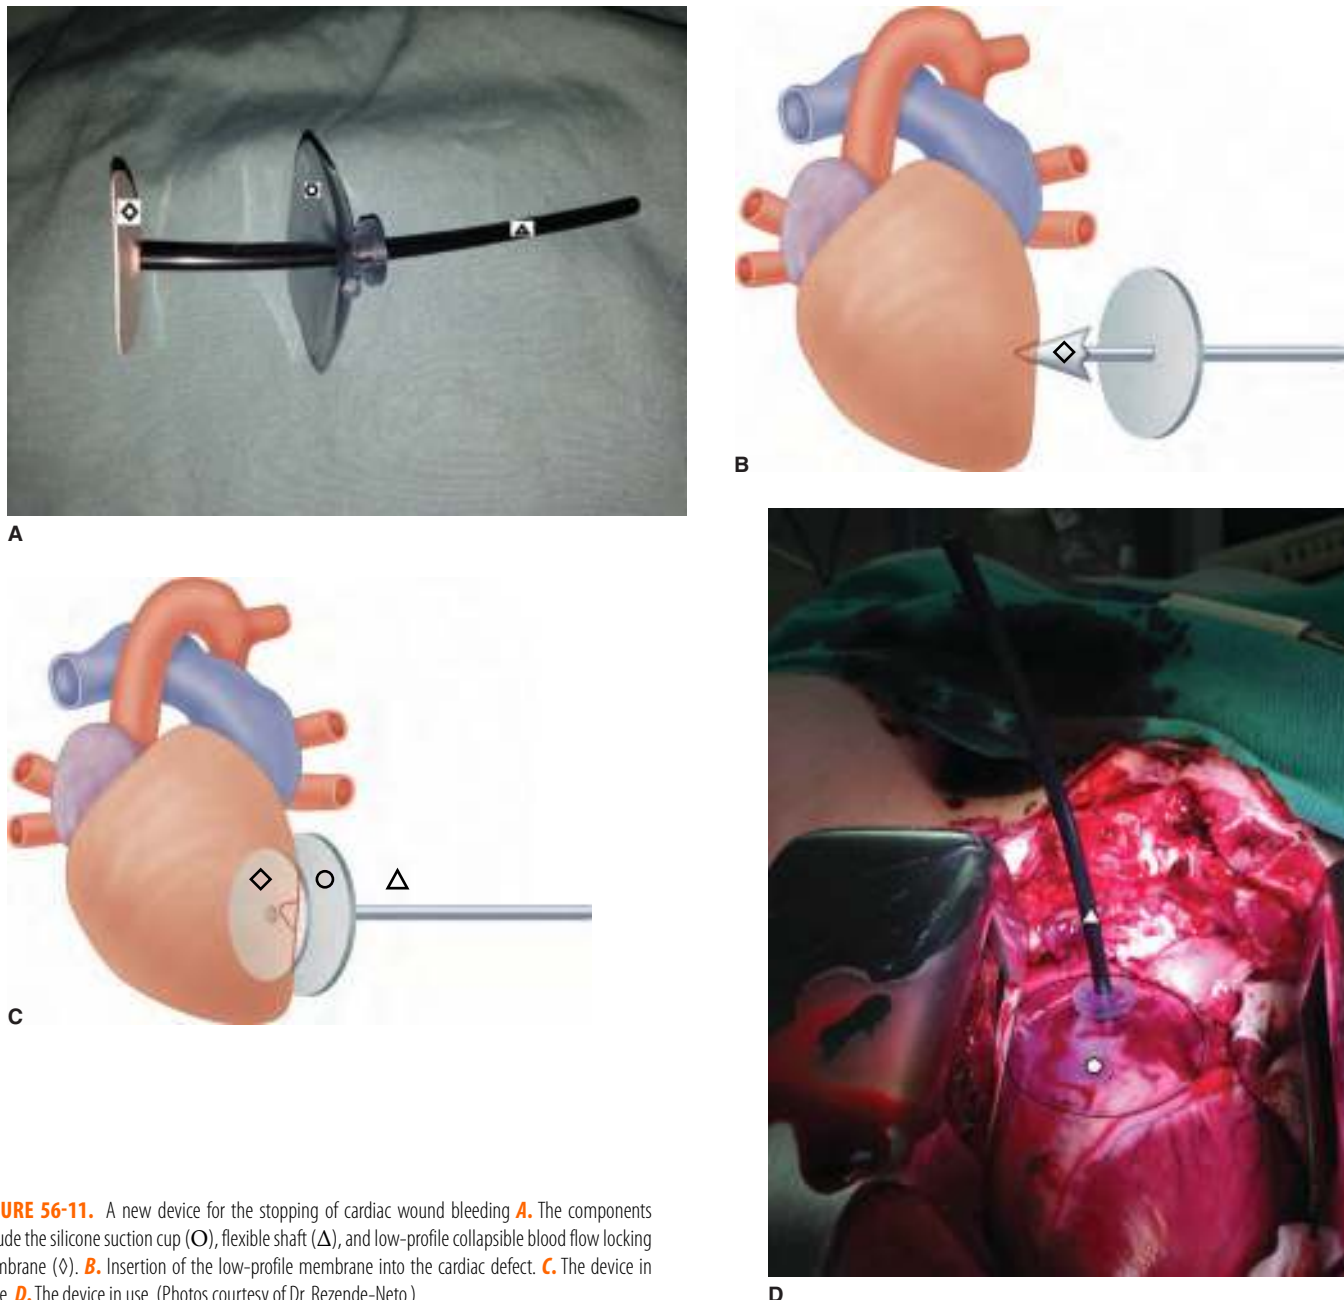

FIGURE 56-11. A new device for the stopping of cardiac wound bleeding **A.** The components include the silicone suction cup (O), flexible shaft (Δ), and low-profile collapsible blood flow locking membrane (◇). **B.** Insertion of the low-profile membrane into the cardiac defect. **C.** The device in place. **D.** The device in use. enlarge a cardiac wound if the cuff pulls through the wound. A drop in cardiac output can result if the cuff obstructs the cardiac valves, impinges on the chordae tendineae, or occupies too much space within the cardiac chamber. Decrease the cuff size by withdrawing some of the saline from the cuff. Suturing is probably associated with the greatest rate of complications. Tearing of the myocardium is a frequently encountered problem. The suture should be tied just tight enough to stop the bleeding and not necessarily achieve complete hemostasis. Care should be exercised to avoid ligation of the major coronary vessels and their branches. Dysrhythmias can result from occlusion of venous inflow (Sauerbruch maneuver) or injury to the coronary vasculature. If the patient is resuscitated, administer broad-spectrum antibiotics to prevent any potential infectious complication.

SUMMARY

Injuries to the heart can be devastating. The role of the Emergency Physician is to rapidly and temporarily control bleeding and ensure the transport of the patient to the Operating Room for definitive repair. The Emergency Physician must be versed in the techniques used to repair cardiac wounds and resuscitate the patient if there is a delay in transporting the patient to the Operating Room.

Hilum and Great Vessel Wound Management

Eric F. Reichman

INTRODUCTION

Injuries to the thoracic great vessels can be a significant cause of morbidity and mortality. Large vessels in the hilum of the lung include the pulmonary artery and vein. The great vessels also include the vena cava, aorta, innominate artery, subclavian artery, and subclavian vein. The mortality from injuries to the subclavian artery is approximately 5% if patients who are moribund on admission to the Emergency Department are excluded.¹ However, the mortality from injury to the vena cava and the pulmonary vessels is over 60%.² While over 85% of patients with penetrating injuries to the thorax are stable, the remainder present in varying levels of hypovolemic shock. They may have bled externally or into the chest. Each hemithorax can hold up to one-half of an individual's blood volume. In these cases, an Emergency Department thoracotomy may be performed for hypovolemic shock.

ANATOMY AND PATHOPHYSIOLOGY

Injury to the thoracic great vessels may be due to blunt trauma, diagnostic procedures, iatrogenic causes, or penetrating trauma. Crush injuries, deceleration injuries, motor vehicle versus pedestrian collisions, and penetrating thoracic injuries may all signify an injury to a thoracic great vessel. The vessels that are most commonly injured include the aorta, innominate artery, pulmonary vein, and venae cavae.

The portable anteroposterior chest radiograph is the initial radiographic screening. It may reveal loss of the aortic knob contour, left-sided pleural effusions, mediastinal widening, nasogastric tube deviation, or tracheal deviation, all of which suggest injury to a great vessel. Other findings suggestive of great vessel injury include depression of the left mainstem bronchus, left apical capping, narrowing of the carinal angle, sternal fractures, opacification of the aortopulmonary window, and widening of the paraspinous stripe.

Numerous physical examination findings are suggestive of a thoracic great vessel injury. Asymmetric pulses or unequal blood pressures between the extremities are quick and simple to evaluate. Hypotension may be due to internal or external hemorrhage. Steering wheel contusions, sternal fractures, thoracic spine fractures, and a left-sided flail chest signify potential intrathoracic injury. A thoracic outlet hematoma or a hoarse voice can occur from injury to the aorta or one of its major branches. Paraplegia may be due to hypotension or an aortic disruption.

INDICATIONS

Attempts should be made to control any laceration or rupture of the thoracic great vessels.^{3,4}

CONTRAINDICATIONS

There are no absolute contraindications to temporarily controlling any hemorrhage from a thoracic great vessel after performing a thoracotomy (Chapter 54). The thoracotomy should not be performed if the patient has obvious signs of death, no vital signs in the field, or no vital signs for over 15 minutes. Refer to Chapter 54 for a discussion in which a thoracotomy is contraindicated, as any hilum or great vessel repair is also contraindicated. A pericardial tamponade or cardiac injury may require management prior to managing

FIGURE 57-1. Examples of several atraumatic vascular clamps.

a great vessel injury. There is a less than 1% chance of survival if the patient has multiple gunshot wounds to the torso.^{5,6} It is up to the discretion of the treating physician in cases of multiple gunshot wounds to the torso if a thoracotomy is to be done due to the generally accepted unsalvageability.^{5,6} It is also contraindicated if the patient is clearly deceased.

EQUIPMENT

- 3–0 Prolene suture
- Foley catheters, sizes 14 to 20 French
- 10 inch needle driver
- Satinsky, or other, atraumatic vascular clamp (**Figure 57-1**)
- Sterile saline
- 20 mL syringe
- Laparotomy pads
- Gauze 4 × 4 squares
- Umbilical clamp
- Hemostats

PATIENT PREPARATION

There is no preparation required other than performing an anterolateral thoracotomy (Chapter 54). The patient should be intubated, ventilated with 100% oxygen, and fully monitored (i.e., telemetry,

a noninvasive blood pressure cuff, and pulse oximetry). Instruct a nurse to administer intravenous broad-spectrum antibiotics that cover skin flora, gram-positive organisms, and gram-negative organisms. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. Although time is of the essence and this is an emergent procedure, aseptic technique should be followed. A thoracotomy must first be performed. Refer to Chapter 54 for the complete details of a thoracotomy.

TECHNIQUES

DIGITAL OCCLUSION

Digital pressure may be used to control small lacerations of the thoracic vena cava. It will provide adequate hemostasis while repairing the wound. **Place a fingertip over the defect. Do not place a finger in the defect.** Place horizontal mattress sutures using 3–0 Prolene to close the defect. Unfortunately, the fingertip interferes with visualization of the wound and places the Emergency Physician at risk for a needlestick injury. The fingertip will have to be intermittently removed to place the sutures.

Digital pressure and rapid transport to the Operating Room is the most practical method of dealing with injuries to the subclavian vessels. These vessels are extremely difficult to control through a traditional anterolateral thoracotomy incision. If digital pressure is ineffective, pack the apex of the thoracic cavity with laparotomy pads or gauze squares and apply compression from below.

FOLEY CATHETER TECHNIQUE

One may occlude a wound to a great vessel by inserting a Foley catheter into the vessel, inflating the cuff, and placing it under gentle traction (**Figure 57-2**). As with digital occlusion, this is only a temporizing measure. Inflate the cuff of the Foley catheter with sterile saline to check its integrity and look for leaks. Deflate the cuff. **Place a hemostat on the Foley catheter proximal to the cuff. This will prevent air from being drawn through the catheter and causing an air embolism.**

Identify the location of the vascular injury. Insert the catheter through the wound until the cuff is within the vessel (**Figure 57-2A**). Open the hemostat, inflate the cuff with 5 to 10 mL of sterile saline, and reclamp the Foley catheter. **This step should be completed quickly to prevent air from being drawn through the catheter. Do not overinflate the cuff so that it occludes flow through the vessel. Apply gentle traction to the catheter (Figure 57-2B). Apply just enough traction to mostly occlude the wound and slow the**

FIGURE 57-2. The Foley catheter technique to occlude an injury to a great vessel. **A.** The catheter is inserted through the wound and into the vessel. **B.** The cuff is inflated and gentle traction (arrow) is applied to occlude the wound with the cuff. **C.** An umbilical clamp is placed to prevent the catheter from migrating inward.

FIGURE 57-3. A Satinsky vascular clamp may be used to partially occlude the great vessel and isolate the injury.

bleeding. Do not try to provide complete hemostasis. Providing complete hemostasis can result in excessive traction on the catheter causing the cuff to pull through the wound. This can enlarge the wound and further injure the vessel. Place an umbilical clamp or hemostat on the catheter just outside the vessel to prevent it from migrating into the vessel (**Figure 57-2C**).

The Foley catheter technique is simple and effective. It avoids the problems associated with digital occlusion. It does not interfere with visualization of the wound or the simultaneous performance of cardiac massage. Intravenous catheter tubing may be inserted into the lumen of the Foley catheter to infuse crystalloid solutions or red blood cells directly into the heart and central circulation.

CROSS-CLAMPING TECHNIQUE

Injuries to the thoracic great vessels can bleed profusely and are difficult to control. Digital occlusion is often ineffective. An

atraumatic Satinsky vascular clamp, or other atraumatic vascular clamp (**Figure 57-1**) in the thoracotomy tray, can be placed to partially occlude a great vessel and isolate the injury (**Figure 57-3**). This will provide temporary hemostasis until definitive repair in the Operating Room.

Large wounds and complete transections are difficult to manage. Injuries to the pulmonary vasculature in the region of the hilum are most expeditiously controlled by placing an atraumatic vascular clamp across the respective hilum.⁷ Grasp the hilum between the thumb and the forefinger. Place the clamp carefully around the entire hilum. Take care not to injure the pulmonary parenchyma or the vessels any further. Vascular injuries may be controlled by placing a cross-clamp proximal to the injury and occluding the backbleeding with additional clamps (**Figure 57-4**). These patients should be immediately transported to the Operating Room to be placed on bypass and repair the injuries. **It is not recommended for the Emergency Physician to suture great vessel injuries in an attempt to repair them.**

AFTERCARE

If the patient is resuscitated, cover the thoracotomy wound with a saline-moistened gauze and a simple dressing. Administer broad-spectrum antibiotics if not done previously. Immediately transport the patient to the Operating Room for definitive repair of the great vessel injury and any other injuries by a Trauma or Cardiovascular Surgeon.

COMPLICATIONS

The complications associated with digital pressure include extending the injury if the procedure is not performed carefully. Inaccurate digital control can lead to unnecessary loss of blood during transport of the patient to the Operating Room. Foley catheters, if pulled too tightly, can become dislodged and restart troublesome bleeding. They can also enlarge a wound if the cuff pulls through the wound. The cuff may obstruct flow through the vessel and compromise cardiac output. Decrease the cuff size by withdrawing some of the saline from the cuff. An overly rough mobilization and clamping can increase the size of the injury and cause massive bleeding. Cross-clamping of the aorta and/or pulmonary artery will obstruct peripheral blood flow. The vessel must be repaired or the patient placed on bypass to prevent anoxia and permanent neurologic dysfunction.

FIGURE 57-4. Cross-clamping of vascular injuries. **A.** Cross-clamp the great vessels to provide temporary hemostasis. **B.** Distal vessels must also be cross-clamped to prevent backbleeding.

SUMMARY

Injuries to the thoracic great vessels carry a high mortality as bleeding occurs unimpeded into the pleural space. The survival of the patient depends on their presenting condition as well as the speed and accuracy with which the intrathoracic hemorrhage is controlled.

Thoracic Aortic Occlusion

Eric F. Reichman

INTRODUCTION

Temporary thoracic aortic occlusion should be performed during an Emergency Department thoracotomy for hypovolemic shock. It preserves cerebral and coronary artery perfusion pressure.¹ The blood flow to the viscera below the cross clamp, however, falls to less

than 10% of baseline flow.² This can be advantageous since it stops distal hemorrhage, but it can later result in the undesired metabolic consequences of acidosis, hyperkalemia, and multiple organ system failure.^{3,4} The use of the Emergency Department thoracotomy is likely to decrease as the resuscitative endovascular balloon occlusion of the aorta (REBOA) technique (Chapter 74) becomes more established and available.

ANATOMY AND PATHOPHYSIOLOGY

The aorta begins at the left ventricle and gives rise to the arteries of the body, directly or indirectly (**Figure 58-1**). It leaves the ventricle and is directed upward as the ascending aorta. It arches to the left and backward at the level of the sternal angle to become the aortic arch. The arch gives rise to the brachiocephalic trunk, left common carotid artery, and left subclavian artery. The aortic arch is directed inferiorly after giving rise to the left subclavian artery and is known as the descending aorta. The descending aorta is subdivided into the thoracic portion above the diaphragm and the abdominal portion below the diaphragm. It descends through the posterior mediastinum, lying first against the left side of the fifth thoracic vertebral body. As it descends, it gradually approaches the midline of the 12th thoracic vertebral body, at which point it passes through the diaphragm.

The esophagus is a thin, muscular tube measuring approximately 2.0 to 2.5 cm in diameter. It descends along the vertebral bodies. It travels forward, away from the vertebral bodies, and to the right at the level of the ninth thoracic vertebral body. It traverses the diaphragm at the level of the 10th thoracic vertebral body. It lies posterior and medial to the descending thoracic aorta throughout most of its course. It migrates as it travels distally, so that its lower part lies in front of the aorta just above the diaphragm (**Figure 58-1**).

INDICATIONS

The primary reason to occlude the descending thoracic aorta is to temporarily direct blood flow from below the diaphragm to preserve flow to the brain and heart. The descending thoracic aorta may be occluded in patients with penetrating thoracic or abdominal trauma in which hypovolemic shock and clinical deterioration are

FIGURE 58-1. Anatomy of the aorta and surrounding structures of the mediastinum and left hemithorax. The mediastinal pleura has been removed to visualize the underlying structures.

not responsive to aggressive fluid resuscitation and blood transfusion. These patients should have the appropriate indications to perform an anterolateral thoracotomy (Chapter 54). The thoracic aorta may also be occluded immediately prior to laparotomy if the patient has a tense abdomen filled with blood. The abdominal incision will decompress the abdomen and result in hypotension, decreased coronary and cerebral perfusion pressure, exsanguination, and death. Uncontrollable hemorrhage anywhere below the diaphragm can be controlled by temporarily occluding the descending thoracic aorta.

CONTRAINDICATIONS

There are no absolute contraindications to temporarily occluding the descending thoracic aorta after performing an anterolateral thoracotomy. The thoracotomy should not be performed if the patient has obvious signs of death, no vital signs in the field, or no vital signs for over 15 minutes. Refer to Chapter 54 for a discussion in which a thoracotomy is contraindicated, as thoracic aortic occlusion is also contraindicated. It is also contraindicated if the patient is clearly deceased.

EQUIPMENT

- Satinsky, or other, atraumatic vascular clamp (Figure 58-2)
- Metzenbaum scissors
- DeBakey or large Kelly clamp
- Nasogastric tube
- Aortic compressor, Conn or homemade
- Gauze 4 × 4 squares

PATIENT PREPARATION

No preparation is required other than that of performing a thoracotomy and a pericardiotomy (Chapter 54). The patient should be intubated, ventilated with 100% oxygen, and fully monitored (i.e., telemetry, a noninvasive blood pressure cuff, and pulse oximetry). Insert a nasogastric tube. Instruct a nurse to administer intravenous broad-spectrum antibiotics that cover skin flora, gram-positive organisms, and gram-negative organisms. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. While time is of the essence and this is an emergent procedure,

FIGURE 58-2. Examples of several atraumatic vascular clamps.

aseptic technique should be followed. Perform the left lateral thoracotomy (Chapter 54).

TECHNIQUE

Identify the aorta by palpation. It is often easier to identify and isolate the aorta just above the diaphragm. In this location, the aorta is slightly separated from the adjacent esophagus. Elevate the left lung with the nondominant hand superiorly and medially. Instruct an assistant to maintain the lung out of the way. Place the dominant hand through the thoracotomy incision and into the posteroinferior recess of the thoracic cavity. Advance the hand along the diaphragm and toward the midline. The fingers will first encounter the vertebral bodies. The next palpable structure is the aorta. It lies anterior to the vertebral bodies. The aorta may be difficult to palpate if it is collapsed in the patient with hypovolemic shock. In the elderly, the aorta may be significantly calcified, which helps to identify it despite hypovolemia. The aorta is covered by the mediastinal pleura. Place the thumb and index finger of the nondominant hand over the aorta just above the diaphragm.

Isolate the aorta. Bluntly dissect open the mediastinal pleura overlying the aorta with a DeBakey clamp or a large curved Kelly clamp. **Never use a scalpel to open the mediastinal pleura, as it may lacerate the aorta.** Some physicians may prefer to use a Metzenbaum scissors to dissect and open the mediastinal pleura. Identify the aorta by palpation. Bluntly separate the aorta from the esophagus with the dominant hand. It may be extremely difficult to separate the aorta from the esophagus in the patient with hypotension, hypovolemia, and/or shock. Place a nasogastric tube if this has not been done previously. The nasogastric tube will be palpable within the esophagus and can be used to identify the esophagus. Hook the dominant index finger around the aorta. **Use the finger to separate the aorta from the vertebral bodies. The dissection should not be extensive. It should free approximately 3 to 4 cm of the descending thoracic aorta.**

DIRECT COMPRESSION

Direct compression of the aorta is fast and simple, it does not interfere with the operative field, and it causes less damage than the application of a clamp. Digital compression is often ineffective. Aortic compression devices have a unique shape to occlude the aorta atraumatically by compressing it against the vertebral bodies. It may be applied before or after the aorta is isolated. Homemade compression devices may use rubber tubing to occlude the aorta (Figure 58-3A).⁵ The Conn compressor is commercially available and uses a metal plate to occlude the aorta (Figure 58-3B). Place the distal end of the compression device against the distal descending thoracic aorta (Figure 58-3C). Apply downward pressure to occlude the aorta. The degree of occlusion can be controlled by increasing or decreasing the pressure applied to the aorta.

CROSS-CLAMPING

The descending thoracic aorta is most commonly occluded with an atraumatic or Satinsky vascular clamp. Aortic compression devices are rarely available in Emergency Departments or on thoracotomy trays. The aorta must first be separated and isolated from the esophagus, as described above. Place an index finger behind the descending thoracic aorta to elevate it away from the underlying esophagus (Figure 58-4A). Place the Satinsky or other atraumatic vascular clamp over the aorta. One jaw should be posterior to the aorta and adjacent to the index finger while the other jaw is anterior to the aorta. Clamp the aorta and remove the index finger (Figure 58-4B).

FIGURE 58-3. Aortic compression. **A.** The homemade aortic compression device.⁵ **B.** The commercially available Conn compressor. **C.** The aorta is compressed between the distal end of the compression device and the thoracic vertebral body.

It is imperative not to clamp the esophagus. Do not clamp the aorta before it is dissected from the esophagus. Esophageal injury can lead to perforation, ischemia, and sepsis if the patient is resuscitated. Ideally, the clamp should be placed under direct visualization of the aorta. Unfortunately, this is not always practical. The index finger under the aorta can confirm the proper isolation of the aorta and the proper position of the jaws of the clamp before the aorta is cross-clamped.

AFTERCARE

If—after the thoracotomy, open cardiac massage, and aortic cross-clamping—there is return of a cardiac rhythm and a carotid pulse, the patient must be taken immediately to the Operating Room for definitive treatment. Cover the thoracotomy wound with a saline-moistened gauze and a simple dressing. The patient's blood pressure in the upper extremity should be monitored every 30 to 60 seconds after the aorta is occluded. This is best accomplished with the use of an arterial line (Chapter 72). An elevated blood pressure can result in a hemorrhagic stroke or left ventricular failure. Elevated blood pressure will require intermittent release of the aortic occlusion and/or pharmacologic management. Parenteral broad-spectrum

antibiotics should be administered to prevent infection if not done previously.

COMPLICATIONS

Intercostal arteries arising from the thoracic aorta can be damaged during mobilization of the aorta. This will result in troublesome bleeding that requires operative control. The aorta, vena cava, or the esophagus can be damaged by the clamp. Aortic cross-clamping can precipitate hypertension, stroke, and left-sided heart failure. If the patient is successfully resuscitated, this should be dealt with by periodically releasing the clamp. Lack of blood flow through the artery of Adamkiewicz will cause ischemia of the distal spinal cord. There is a 5% incidence of paraplegia when the blood supply to the distal aorta and spinal cord is disrupted.^{6,7} This incidence increases dramatically when the spinal cord is ischemic for more than 30 minutes.⁷

Aortic cross-clamping causes visceral ischemia. The gut loses its barrier function and becomes a cytokine-generating organ, which leads to a systemic inflammatory response and multiple organ failure. Renal and liver failure can result from a lack of blood flow.

The organs distal to the aortic clamp become severely ischemic and receive only 10% of the basal cardiac output. The anaerobic

FIGURE 58-4. Aortic cross-clamping. **A.** The mediastinal pleura has been bluntly opened and the aorta isolated from the esophagus. **B.** The Satinsky, or other atraumatic, vascular clamp is placed across the aorta to occlude distal blood flow.

metabolism in these organs generates lactic acid. When the aortic clamp is released, acid and potassium are released into the central circulation and can cause a cardiac arrest. Thus, bicarbonate must be given at this time and the cardiac rhythm monitored carefully.

SUMMARY

Aortic cross-clamping is a useful adjunct to open cardiac massage in hypovolemic shock. It can help salvage patients by increasing coronary and cerebral perfusion. It may be performed as a life-saving and temporizing measure until the patient can be taken to the Operating Room for definitive management. The use of the Emergency Department thoracotomy is likely to decrease as the REBOA technique (Chapter 74) becomes more established and available.

General Principles of Intravenous Access

Daniel Belmont

INTRODUCTION

The practice of Emergency Medicine frequently requires access to a patient's venous circulation. Venous access allows sampling of blood as well as administration of medications, nutritional support, and blood products. Devices such as cardiac pacing wires and pulmonary artery catheters can be introduced into the patient's central venous circulatory system.

Percutaneous, as opposed to surgical, venous access is usually rapid, safe, and well tolerated. An understanding of the various techniques available, the venous anatomy, and the indications for the procedure allows the Emergency Physician to choose the appropriate site, equipment, and method of venous access.

ANATOMY AND PATHOPHYSIOLOGY

Blood vessels have a three-layered wall composed of an internal endothelium, muscle, and a layer of connective tissue (**Figure 59-1**).¹ The muscular layer of a vein is much smaller than that of an artery. Veins can dilate and constrict in response to the pressure within them. Veins with high pressures become engorged and are easier to access. The use of venous tourniquets, dependent positioning, "pumping" via muscle contraction, and the local application of heat or nitroglycerin ointment all contribute to venous engorgement.²

These maneuvers can be used to aid in the identification of a peripheral vein.³

The connective tissue surrounding veins can be a help or a hindrance during attempts at peripheral venous access. Deficient connective tissue permits the vein to "roll" from side to side and evade the needle. Tough connective tissue can impede the entry of a flexible catheter through the soft tissues and into the vein. Connective tissue serves to stabilize the vein and prevent its collapse.

Venous valves are an important aspect of peripheral venous anatomy (**Figure 59-2**).¹ They encourage unidirectional flow of blood back towards the heart. Venous valves prevent blood from pooling in the dependent portions of the extremities due to gravitational forces. **Valves can impede the passage of a catheter through and into a vein. Forcing a catheter past venous valves may damage them and contribute to later venous insufficiency.** Valves are more numerous at the points where tributaries join larger veins and in the lower extremities. Valves are largely absent within the large central veins and the veins of the head and neck.

Veins can be subdivided into central veins and peripheral veins. The important central veins for intravenous access are the internal jugular, subclavian, and femoral veins. Central veins are usually larger than peripheral veins and have fewer tributaries.

Superficial peripheral veins are generally visible beneath the surface of the skin of the extremities and neck. They are often tortuous and continually merge and divide. Peripheral veins are easiest to access at the apex of the "Y" formed when two tributaries merge into a larger vein or where the vein is straight and free of branches (and hence valves) for approximately 2 cm proximal to the site of puncture (**Figure 59-3**). These sites tend to be anchored and "roll" less than other sites. The superficial veins of the upper extremity

FIGURE 59-1. Comparative anatomy of an artery and a vein. **A.** The generic blood vessel. **B.** A muscular artery. **C.** A vein. Note the vein's thinner wall with fewer myocytes and elastic fibers. This is indicative of the lower pressure within veins compared to arteries.

FIGURE 59-2. Venous valves. Cross-section of converging veins demonstrating the valve leaflets that only permit forward flow, proximally, toward the right heart. The arrows represent the directional flow of blood.

are preferred to those of the lower extremity for peripheral venous access. Indwelling catheters in the upper extremity interfere less with patient mobility and the risk of phlebitis is lower.¹

The depth of the vein beneath the epidermis will affect the ease with which it may be accessed. Very superficial veins are often small, fragile, and easily passed “through-and-through” with a needle forming a hematoma. The deeper veins are often not visible and must be located by surface landmarks, palpation, or ultrasound (US).⁴ The angle of insertion of the needle must be varied depending on the depth of the vein being punctured (**Figure 59-4**). A shallow angle of approximately 30° to 45° should be used for most small and superficial veins (**Figure 59-4A**). A more

FIGURE 59-3. Preferred venous access sites. Preferred sites (open circles) are at the apex of converging veins or in the middle of a long straight vein. Sites just distal to branching or convergence of veins (red X) are best avoided due to the presence of valves and the difficulty in threading a cannula.

FIGURE 59-4. The angle between the needle and the skin must be varied based on the depth and diameter of the target vein. **A.** A shallow angle must be used for small and superficial veins. **B.** A steeper angle must be used for deeper veins. **C.** A butterfly-type needle permits the shallowest angle of entry for very small and superficial veins.

obtuse angle of approximately 60° should be used to access deeper veins (**Figure 59-4B**). This steeper angle allows the vein to be penetrated within a reasonable horizontal distance from the skin puncture site. Very small and superficial veins should be entered at a very acute angle of approximately 15° to 30° (**Figure 59-4C**).

INDICATIONS

Venous puncture (i.e., venipuncture) with a needle is indicated only for the sampling of venous blood. Medications may be administered as a one-time dose via this technique. The risk of medication extravasation with this technique is high and has fallen out of favor.

Venous cannulation is indicated for repeated sampling of venous blood. It is also performed for the administration of intravenous medications, fluid solutions, blood products, and nutritional support. The specific indications for peripheral venous access, central venous access, and the various techniques of venous cannulation are discussed below and in Chapters 60 through 64.

CONTRAINDICATIONS

Veins should not be accessed through infected skin. A vein proximal to a running venous infusion should not be used for venous blood sampling. The blood sample will be tainted or diluted by the infused solution. The hole in the vein may allow blood, infused solutions, and medications to extravasate into the surrounding tissues.

Venipuncture and venous cannulation of veins in an extremity with an arteriovenous fistula should be avoided. Veins in the upper extremity that may be needed for arteriovenous fistula construction for hemodialysis in the near future should not be punctured unless absolutely necessary. Scarring of the vein may complicate later surgical procedures.

CATHETER MATERIALS

Indwelling catheters are made of flexible polymers that are less likely to break or erode through the blood vessel wall than more rigid materials (e.g., steel or glass). Polymer resins, Teflon, and polyurethane are commonly used materials. Latex-containing products should be avoided due to the risk of allergic reactions. Polyurethane catheters may be weakened by alcohol-based solutions.¹ Do not infuse these solutions through polyurethane catheters.

All catheters are potentially thrombogenic. They should be left in place only as long as needed. Catheters impregnated with antiseptics (e.g., chlorhexidine and silver sulfadiazine) are commercially available and may decrease the incidence of catheter-related sepsis.⁵ Chlorhexidine has been associated with immediate hypersensitivity reactions, most commonly in persons of Japanese descent.⁶ **Avoid silver sulfadiazine in sulfa-sensitive patients.** Catheters are available that, when immersed briefly in an antibiotic solution prior to insertion, allow an antibiotic to bind to the catheter surfaces. These catheters may reduce the risk of infection with organisms susceptible to the chosen antibiotic.

FLUID-FLOW CONSIDERATIONS

The diameter and the length of the infusion device will affect the flow rate through the catheter.⁷ Viscous fluids (e.g., blood products and albumin) will infuse more slowly than less viscous fluids (e.g., saline). These relationships can be seen in the solution of Poiseuille's equation for ideal fluid flow through a cylindrical tube:

$$\text{Flow rate } \alpha \frac{(\pi \times \text{catheter radius}^4 \times \text{pressure gradient along the tube})}{(8 \times \text{tube length} \times \text{dynamic fluid viscosity})}$$

The pressure gradient and resistance to flow are inversely proportional to the length of the tubing. **Changes in catheter diameter (i.e., catheter size) will have the most effect on flow rates.** The flow rate increases to the fourth power as the catheter's internal radius increases. Flow rates can be maximized by using the largest internal diameter (i.e., smallest gauge) catheter that will fit inside the chosen vein. Large-bore venous catheters are preferred for the highest-volume rapid fluid resuscitations, particularly of viscous blood products. Flow rates decrease as catheter length increases. **Use of the shortest possible catheter to access the chosen vein will permit the highest fluid infusion rates.** External pressure applied to the bag of infusion solution will linearly increase the flow rate.

Fluids must be administered quickly in some patients (i.e., acute blood loss, hypothermia, hypovolemia, and shock). Many devices have been developed to increase the fluid management to these patients quicker than the drip of the intravenous (IV) tubing. These include level 1 infusers, IV pumps, the LifeFlow device, and the pressure bag (Figure 59-5). Some of these devices have a fluid warmer in line.

Level 1 devices infuse blood products and fluids very quickly (Figure 59-5A). Flow rates range from 30 to 1400 mL/min. They usually contain a heat exchanger that can be turned on and off with a switch. The heating of fluid uses a countercurrent of 42°C to deliver fluid of 36°C to 40°C. A gas vent filter removes micro-bubbles of gas from the IV line due to heating of the fluids. Some devices have an integrated air detector that detects the presence of air, alarms, and automatically stops the flow of fluid to the patient. One nurse or technician is usually dedicated to operate the level 1 infuser.

In 2017, the 410 Medical Company (Durham, NC) released the LifeFlow Rapid Infuser (Figure 59-5C). It infuses 500 mL in 2.5 minutes. It is a hand-powered device. The dedicated person squeezes the trigger to pump 10 mL of fluid into the IV catheter. Release of the trigger loads 10 more mL into the device in anticipation of pressing the trigger again. The fluid flow resistance is felt through the handle. The disadvantages to this device are the manual hand pumping, no fluid warming capacity, and fatigue of the operator. The advantages of this device are its costs, single use, small size, and portability.

LOCATING A PERIPHERAL VEIN

Identifying a peripheral vein can sometimes be quite difficult. Dilating a vein (i.e., venodilation) can make a vein larger, easier to identify, and easier to access. These techniques are easy to perform.

Several venodilation techniques do not require any special equipment.⁸ Place the extremity in a dependent position.⁹ This position allows gravity to decrease venous return and dilate the veins.¹⁰ Gently tap the skin in the area to dilate the underlying veins.^{9,10} The exact mechanism of how this works is not known. It may be due to the release of chemical mediators, stimulation of nerve fibers, or a combination of both. Instruct the patient to open and close their hand. The muscular contractions of the forearm muscles increases arterial inflow distally while venous outflow is inhibited by the tourniquet.^{9,11-13} Try to "milk" the veins in a distal direction. Apply your fingers over the skin, press downward, and then move the fingers distally to "milk" or back-flow the blood and dilate the distal veins.⁹ Apply a warm compress, heat pack, or warm towel or submerge the extremity in warm water to dilate the veins. Be careful to not use too hot of a temperature to prevent burning the patient.

Several commercially available devices can be used to produce venodilation.^{8,14} The Esmarch Bandage is a tourniquet system used to exsanguinate a limb prior to surgery. Apply it to the upper extremity starting proximally and wrap it distally, the reverse of applying it to exsanguinate the extremity. It will result in blood pooling in the distal veins and subsequent venodilation. The Rhys-Davies Exsanguinator can also be placed proximal to distal to pool blood distally and cause venodilation.¹⁵ This device is usually not available in the Emergency Department. A vacuum device was developed to aid in obtaining venous access.^{16,17} It is cumbersome and often not available in the Emergency Department.

Bedside US is being taught in all Emergency Medicine residencies. It is also taught in medical schools, paramedic programs, and air ambulance services. There are many advantages to using US to facilitate IV access. The use of US has been shown to make finding a vein easier.^{4,18} US allows faster IV access in patients less than 3 years of age.¹⁸ It can be used in patients with difficult IV access.^{19,20} US use avoids central venous line placement.²¹ Refer to Chapter 64 for more information on US-guided vascular access.

Another technique to finding a larger peripheral vein to cannulate is to place a small gauge intravenous catheter in a distal vein (typically the hand), keep the tourniquet in place, and infuse a small amount of crystalloid (e.g., 60 to 300 mL) through the catheter. The

FIGURE 59-5. Examples of IV fluid flow devices. **A.** Level 1 infuser. **B.** IV infusion pump. **C.** LifeFlow Rapid Infuser. **D.** Pressure bag.

fluid will flow through the canalized and collateral veins distending all the veins distal to the tourniquet.²²

Topically applied pharmaceuticals can be used to dilate the dorsal hand veins.²³⁻²⁵ Topical nitroglycerine ointment has been used for many years. Apply 1 inch of the ointment and rub it into the skin on the dorsal hand. Use gloves while applying the ointment to prevent the side effects of a headache or hypotension to the healthcare provider. Allow the ointment to sit for 2 minutes and then completely wipe it off the skin. Clean any residual nitroglycerine ointment from the skin with an alcohol swab. Identify a vein by palpation. Topical nifedipine is an alternative but is not currently available in the United States.

In recent years, numerous commercial devices have become available to visualize veins. These devices reduce the number of

attempts and increase the success rate but increase the time to obtain IV access.²⁶ The major drawbacks of these devices are their cost. The VeinViewer (Christie Medical Holdings, Inc., Memphis, TN) uses polarized near-infrared light from light-emitting diodes to penetrate the skin and subcutaneous tissues (**Figure 59-6**).²⁷⁻²⁹ It is available in hand-held and mounted versions. The device projects the underlying blood-filled veins onto the skin using a visible green light. The AccuVein AV300 (AccuVein LLC, Cold Spring Harbor, NY)³⁰ and the Veinlite (TransLite, Sugar Land, TX)³¹ are similar devices but are only available in the hand-held version (**Figures 59-7 and 59-8**). The Veinlite is available in several sizes and versions. The Venoscope (Venoscope LLC, Lafayette, LA) is a hand-held device that is also available in a neonatal version (**Figure 59-9**). Evena Medical (Roseville, CA) has developed a glasses vein finder

and a mounted version (**Figure 59-10**). Oxy-Amp (2AI Labs, US Virgin Islands) makes several versions of glasses (**Figure 59-11**). The VeinSite (VueTek, Gray, ME) fits over the head and leaves both hands free (**Figure 59-12**).

ANESTHESIA

The use of anesthesia prior to venipuncture or venous cannulation is much appreciated by the patient, especially if the patient is a child. The use of local anesthetic solution will decrease the pain of venous access. The pain of injection can be just as uncomfortable as the venous access procedure. The application of a topical anesthetic (e.g., ELA-Max [Ferndale Laboratories, Ferndale, MI] or EMLA [AstraZeneca, Wilmington, DE]) is designed to enhance transdermal absorption and requires approximately 30 to 60 minutes to adequately anesthetize the skin and subcutaneous tissues. This time delay limits their use in the Emergency Department (Chapter 154).

Numerous alternative anesthesia methods can be considered (Chapter 154). These are rarely available or used in the Emergency Department. Local anesthetic absorption through the skin can be enhanced to decrease the time it takes to provide anesthesia. These methods include using sound energy (sonophoresis), electrical energy (iontophoresis), and epidermal tape stripping.³²⁻³⁴ A portable, hand-held laser used prior to the application of topical anesthesia for 5 minutes effectively reduces the pain of venous access.^{35,36} Topical vapocoolant spray will briefly anesthetize the skin long enough to allow for venous access.³⁷⁻⁴³ Local anesthetic patches that are heat activated to increase transdermal absorption of the local anesthetic agent

in approximately 20 minutes have been found to be effective.⁴⁴ Needleless jet injections of local anesthetics effectively anesthetize the skin and subcutaneous tissues.⁴⁵⁻⁴⁷ One study questioned if the anesthesia was due to the local anesthetic agent or the jet injection procedure

itself as the placebo group was just as effective in terms of anesthesia.⁴⁶ **The main advantages of these techniques, compared to injectable anesthetics, are the lack of pain during the application and the lack of tissue distortion making identification of the vein difficult.**

FIGURE 59-13. Venous access devices. From top to bottom: butterfly needle with extension tubing, hollow needle, catheter-over-the-needle (i.e., angiocatheter), catheter-through-the-needle, and the guidewire-guided catheter.

VENIPUNCTURE

Five types of devices are used for vascular access (**Figure 59-13**). There are numerous variations of these devices. The butterfly needle and hollow needle are used for venipuncture. Blood may be withdrawn using a butterfly-type needle (**Figure 59-14**) or a standard hypodermic needle. The butterfly needle, attached to a short length of plastic tubing, allows for greater control while accessing small and superficial veins. It is often too short to reach deeper veins. Versions with an integral sheath to minimize accidental needle-stick injuries are available (**Figure 59-15A**). A butterfly needle appears to decrease the hemolysis when compared to IV catheters.^{48,49}

Venous blood sampling can be accomplished by one of several methods. Blood may be allowed to drip from the open end of the butterfly extension tubing into small-volume collection tubes for pediatric patients. Some form of suction is used to withdraw the blood more rapidly in older children and adults. A syringe or vacuum tube may be used (**Figure 59-16**). Vacuum tubes reduce the risk

of needle-stick injuries. The amount of suction provided is fixed and may result in hemolysis of the specimen and cause small veins to collapse. Syringe aspiration allows greater control over the amount of suction applied. Large syringes can be difficult to manipulate while maintaining the tip of the needle within the vein. Use a 5 to 10 mL syringe, as larger syringes result in hemolysis of the specimen and collapse of the vein. **The needle used to transfer the specimen from the syringe to the laboratory tubes can cause a needle-stick injury.**

The Touch Activated Phlebotomy (TAP) device (Seventh Sense Biosystems, Medford, MA) was developed for venipuncture (**Figure 59-17**). The base of the device uses adhesive to stick and form an airtight seal on the skin of the upper arm. Pushing the button on the top of the device activates 30 thin needles that penetrate the skin. This micropuncture causes no pain, takes 2 minutes, and obtains 100 μ L of blood. Blood is collected in a reservoir with anti-coagulant. The device has an indicator for when the blood collection is complete. The laboratory can extract the sample from the TAP device and analyze the blood using regular methods.

VENOUS CANNULATION

There are four main techniques of vein cannulation.⁵⁰⁻⁵² The first is the needle-only technique using a butterfly-type needle. This is seldom used today. The catheter-over-the-needle technique is most commonly used for peripheral venous cannulation. The catheter-through-the-needle technique is occasionally used but not very popular. The Seldinger wire-guided technique is most commonly used for central venous access. The major advantages and disadvantages of each technique are summarized in **Table 59-1**.

Identify the vein to be cannulated and the site of the skin puncture. Clean the area of any dirt and debris. Cleanse the skin with isopropyl alcohol, chlorhexidine solution, or povidone iodine solution and allow it to dry. Apply a tourniquet to the extremity, proximal to the venous cannulation site, to engorge the vein.⁵³ Additional engorgement of the vein or the use of a device to locate a vein can aid in the identification of a peripheral vein. **Do not attempt cannulation if the vein cannot be seen, palpated, or otherwise visualized (e.g., US) in the engorged state.** Place a small subcutaneous wheal of local anesthetic solution or some alternative at the skin

A

B

The bottom figure demonstrates the needle inside the safety handle.

puncture site to provide some comfort to the patient. The next step is to cannulate the vein by one of the methods described below.

NEEDLE-ONLY TECHNIQUE

This technique is used occasionally for short-term venous access in young children and elderly patients with fragile veins. This system is prone to malposition and infiltration. **The tip of the needle can easily lacerate the vein if the needle is not secure and allowed to move.**

Grasp and fold the wings of the butterfly needle with the dominant index finger and thumb (**Figure 59-14B**). Briskly insert the needle with the bevel facing upward. Insert it through the skin and into the vein.⁵⁴ A flash of blood will be seen in the tubing when the tip of the needle enters the vein. Carefully advance the needle an additional 3 to 5 mm into the vein. Attach a 5 mL syringe to the extension tubing and aspirate blood. The flow of blood into the syringe confirms proper intravascular placement of the needle. Remove the tourniquet from the extremity. Securely tape the wings of the butterfly needle to

FIGURE 59-16. The Vacutainer.

the patient's skin. Remove the 5 mL syringe, attach intravenous tubing to the catheter, and begin the intravenous infusion.

CATHETER-OVER-THE-NEEDLE TECHNIQUE

The catheter-over-the-needle systems are the ones most commonly used for venous access. The infusion catheter fits closely over a hypodermic needle. The needle and the catheter are advanced as a unit into the vein. These devices are inexpensive (e.g., \$1 to \$4 each), come in a variety of diameters (12 to 24 gauge) and lengths, and are widely available. Versions designed to minimize accidental needle-stick injuries are available, and their use is encouraged (**Figure 59-15B**).⁵⁵

TABLE 59-1 Features of Venous Catheterization Techniques

	Butterfly needle	Catheter-over-the-needle	Catheter-through-the-needle	Seldinger
Diameter of vein punctured compared to catheter diameter	Same	Slightly smaller	Larger	Smaller
Catheter length compared to needle	Same	Slightly shorter	Longer, up to 61 cm (24 inches)	Unlimited
Speed of insertion	Rapid	Rapid	Slower	Slowest
Risk of extravasation	Highest	Low, higher with shorter catheters	Low	Very low
Security of catheter with patient movement	Lowest	Fair to good	Good	Excellent when sutured
Best choice for	Peripheral venous sampling	Peripheral venous infusion	Central venous Access	Central venous access
Can change catheter without new venous puncture?	No	Can use small guidewire and Seldinger technique	No	Yes

Insert the catheter-over-the-needle, with the bevel facing upward, through the skin and into the vein (**Figure 59-18A**).⁵⁴ A flash of blood in the hub of the needle confirms that the tip of the needle is within the vein. Advance the unit an additional 2 to 3 mm to ensure that the catheter is within the vein. Hold the hub of the needle securely. Advance the catheter over the needle until its hub is against the skin (**Figure 59-18B**). Apply pressure with the nondominant index finger over the skin above the catheter to prevent blood from exiting the catheter. Remove the tourniquet from the extremity. Securely hold the hub of the catheter against the skin. Withdraw the needle (**Figure 59-18C**). Remove the tourniquet from the extremity. Attach intravenous tubing to the hub of the catheter and begin the infusion (**Figure 59-18D**). Secure the catheter to the skin with tape.

Placement of these catheters is usually quick and simple. Several considerations should always be kept in mind when using the catheter-over-the-needle technique. Intravascular placement of the system is indicated by a flash of blood in the hub of the needle. Both sides of the vessel may be traversed (i.e., through-and-through) before the practitioner realizes that the needle was within the vein if the patient's venous pressure is very low or if the needle is long and narrow (**Figure 59-19A**). The catheter will not advance if the tip of the needle is withdrawn from the vein.

The catheter will not advance if the tip of the needle but not the catheter is within the vein. The catheter will push the vein off the end of the needle (**Figure 59-19B**). Place a finger just distal to the puncture site. Depress the skin and pull it distally to prevent the vein from "rolling" as the catheter-over-the-needle is inserted into the vein (**Figures 59-19C and 59-19D**).

CATHETER-THROUGH-THE-NEEDLE TECHNIQUE

This technique eliminates the need for a needle that is as long as the catheter and eliminates the possibility of pushing the vein off the end of the needle when the catheter is advanced.⁵⁶ This system is used most commonly for central, rather than peripheral, venous access. Catheters up to 61 cm (24 inches) long are available and allow central venous access from the antecubital vein or the femoral vein. Select a catheter size that is appropriate for the patient and the site of entry. Packaged with each catheter is a needle and a needle guard. The needle will have an inner diameter that is slightly larger than the outer diameter of the catheter. The needle guard has a beveled channel in which the needle resides. The needle guard hinges closed over the needle to hold it securely and prevent the needle from shearing the catheter. Holes in the corners of the needle guard allow it to be sewn to the patient's skin.

FIGURE 59-18. The catheter-over-the-needle technique. **A.** The vein is punctured and blood returns in the needle hub. **B.** The catheter is advanced over the needle and into the vein. **C.** The needle is removed. **D.** Intravenous extension tubing is attached to the catheter.

FIGURE 59-19. Pitfalls of the catheter-over-the-needle technique. **A.** Through-and-through puncture of the vein. **B.** The catheter can push the vein off the needle and prevent cannulation. **C.** Push a finger into the skin distal to the puncture site and pull back (arrow) to keep the vein straight and prevent it from moving. **D.** The nondominant thumb is used to pull the skin and stabilize the vein.

Place the needle on a tuberculin syringe. Insert the needle, with the bevel facing upward, through the skin and into the vein while applying negative pressure to the syringe (**Figure 59-20A**).⁵⁴ A flash of blood in the syringe confirms that the tip of the needle is within the vein. Advance the needle an additional 2 mm to ensure that the tip of the needle is completely within the vein. Grasp and hold the needle securely with the nondominant hand. Remove the syringe with the dominant hand. Immediately place the nondominant thumb over the needle hub to prevent air from entering the vein. Remove the tourniquet from the extremity.

Insert the catheter through the hub of the needle (**Figure 59-20B**). Advance the catheter through the needle until the desired length of catheter is within the vein. **If the catheter will not advance, remove the catheter and needle as a unit. Never withdraw the catheter through the needle. The sharp bevel of the needle may cut the catheter as it is being withdrawn and result in a catheter embolism in the central venous circulation.** Remove the tourniquet from the extremity.

Withdraw the needle over the catheter (**Figure 59-20C**). **Do not allow the catheter to be withdrawn through the needle.** Continue to withdraw the needle until the tip is completely outside the skin. Apply the needle guard over the needle (**Figure 59-20D**). Attach intravenous tubing to the hub of the catheter and begin infusing fluids through the catheter. Secure the catheter and needle guard to the skin with tape and/or sutures.

The main disadvantage of this technique is the possibility of the needle tip shearing off the catheter causing a catheter embolism in the venous circulation. **This can be prevented by not withdrawing the catheter through the needle and applying the needle guard immediately after the needle is withdrawn from the skin.** The contaminated needle must be handled to some extent, creating a potential risk for a needle-stick injury. The needle used for the venipuncture must be larger in diameter than the catheter. This limits the practical diameter of the catheter. The needle punctures a hole in the vessel larger than the catheter and increases the risk of hematoma formation.

FIGURE 59-20. The catheter-through-the-needle technique. **A.** The vein is punctured with the needle. **B.** The syringe has been removed. The catheter is inserted through the needle and into the vein. **C.** The needle is withdrawn over the catheter and completely outside the skin. **D.** The needle guard is attached to secure the needle and prevent it from shearing the catheter.

SELDINGER TECHNIQUE

First described by Seldinger in 1953, this technique allows for the placement of a catheter over a guidewire rather than directly over a needle.⁵⁷⁻⁵⁹ The guidewire used must be longer than the catheter. The needle used to insert the guidewire can be short and of a smaller gauge than the catheter. The catheter type may be changed later without the need for a new venous puncture. Materials needed for catheter insertion are commercially available in a prefabricated kit (Teleflex Medical, Cleveland, OH; Cook Medical Inc., Bloomington, IN).

The Seldinger technique is most commonly used for central venous catheter insertion. It can be used for peripheral venous access if a short, thin guidewire is available. US may be a useful adjunct with this technique (Chapter 64).⁶⁰ All-in-one arterial line kits are commercially available. They are intended for peripheral arterial line placement but can also be used to place catheters in a peripheral vein, the brachial vein, and the external jugular vein.

The Seldinger technique for venous catheter insertion is described briefly here. Refer to Chapter 63 (central venous access techniques)

for a more complete discussion. Choose the puncture site. Prepare the patient for the procedure. Cleanse the skin with isopropyl alcohol, chlorhexidine solution, or povidone iodine solution and allow it to dry. Apply a tourniquet to the extremity, proximal to the venous cannulation site, to engorge the vein.⁵³ The vein may first be located with a small “finder” needle if there is doubt about its exact location. Insert a 25 or 27 gauge needle attached to a 5 mL syringe, with the bevel facing upward, through the skin. Advance the needle while applying negative pressure to the syringe. A flash of blood signifies that the tip of the needle is within the vein. Note the depth and location of the vein based on the depth and direction of the “finder” needle.

Insert the thin-walled introducer needle while applying negative pressure to the syringe. The introducer needle has a tapered hub on the proximal end to guide the guidewire into the needle lumen. **Do not use a standard hypodermic needle as it does not allow for the passage of the guidewire.** A flash of blood in the needle hub signifies that the tip of the needle is within the vein (**Figure 59-21A**). Advance the needle an additional 1 to 2 mm into the vein. Hold the needle securely in place and remove the syringe.

FIGURE 59-21. The Seldinger technique. **A.** The vein is punctured by the needle and blood is aspirated. **B.** The syringe has been removed. The guidewire is inserted through the needle and into the vein. **C.** The needle is withdrawn over the guidewire. **D.** The skin puncture site is enlarged to permit catheter passage. **E.** The catheter is advanced over the guidewire and into the vein. **F.** The guidewire is withdrawn through the catheter.

Occlude the needle hub with a sterile gloved finger. This will prevent air from entering the venous system. Insert the guidewire through the hub of the needle (**Figure 59-21B**). Advance the guidewire to the desired depth, ensuring that it is at least several centimeters beyond the beveled end of the needle. **Never let go of the guidewire with both hands at the same time to prevent loss of the guidewire into the venous circulation.** Hold the guidewire securely in place. Remove the needle over the guidewire (**Figure 59-21C**). Make a small nick in the skin adjacent to the guidewire with a #11 scalpel blade (**Figure 59-21D**). **Direct the sharp edge of the scalpel blade away from the guidewire to prevent nicking the guidewire.**

Place the dilator over the guidewire. Advance the dilator over the guidewire to enlarge the subcutaneous passage for the catheter. Continue to advance the dilator until its hub is against the skin. A twisting motion of the dilator may aid in its advancement through the subcutaneous tissues and into the vein. Withdraw the dilator over the guidewire while leaving the guidewire in place. Advance the catheter over the guidewire until its hub is against the skin (**Figure 59-21E**). A twisting motion of the catheter may aid in its advancement through the subcutaneous tissues and into the vein. Securely hold the hub of the catheter. Remove the tourniquet from the extremity. Remove the guidewire through the catheter (**Figure 59-21F**).

Aspirate blood from the catheter with a syringe to confirm intravenous placement. Flush the catheter with sterile saline or begin an infusion. Secure the catheter to the skin with sutures and tape.

While this technique seems complicated at first glance, it is easy to learn and can be performed in a few minutes by an experienced Emergency Physician.

MIDLINE CATHETERS

Midline catheters are extended dwell catheters (i.e., up to 30 days) that are longer in length than peripheral IV catheters and often shorter than central venous line catheters. They are available in a variety of sizes and lumens (**Figure 59-22**).⁶¹ These catheters can be used for blood sampling, fluid administration, medication administration, and power injection of computed tomography contrast material. They are mostly inserted using the Seldinger method. The flow rate is printed on the hub of the catheter. These catheters are designed to withstand the pressure injectors.

AFTERCARE

The IV catheter needs to be secured. The use of tissue adhesive at the skin puncture site can prevent the catheter from moving. The tissue adhesive prevents dislodgement, infection, occlusion, and phlebitis.⁶² Removal may be problematic. Cover the IV and skin puncture site with a clear dressing.⁶³ Tegaderm dressings are most often used because of convenience. Special clear dressings with cut-outs are available (**Figure 59-23**). These come in a variety of sizes and cost more than a Tegaderm.

FIGURE 59-22. (Continued)

D

The IV Pro (WV IV Pro Inc., Fairmont, WV) can be applied (**Figure 59-24**). This shield was designed to protect the IV site from buildup of bacteria and needle dislodgement. It is a protector and securement device and not a dressing. The clear dome allows site monitoring. Its holes allow airflow and prevent condensation. The device can be used multiple times in the same patient.

Other devices may be added for patient safety. The ivWatch (ivWatch, Williamsburg, VA) monitors the IV site to detect leaks, extravasation, and infiltration (**Figure 59-25**). It is comprised of the patient monitor, a reusable sensor cable, single-use disposable sensor applied next to the IV site, and an AC adapter. The monitor

gives an audible and visual alert. The FIVA (FIVAMed Inc., Halifax, Canada) attaches in-line and alerts to the empty IV fluid bag (**Figure 59-26**).⁶⁴ The FIVA clips onto the IV line and uses infrared to detect air bubbles in the IV tubing and stop the flow. The FIVA gives an audible and visual alert. It is meant to be used for gravity drips and pressure bags and not pumps. The device is only approved for use in Canada for now. The ClearLine (ClearLine MD, Woburn, MA) prevents air bubbles in the IV tubing from entering the patient (**Figure 59-27**). The device uses US to monitor the IV tubing for air bubbles as small as 25 μm . The bubbles are directed into a disposable bag. It works with gravity drips, pumps, and fluid warmers.

COMPLICATIONS

Complications specific to each technique and site are discussed more fully in the following chapters. Venous catheters should be assessed immediately after their placement and reassessed frequently. The assessment must include the skin puncture site, catheter function, the extremity distal to the catheter, and the patient’s overall condition. Some of the common problems are noted in **Table 59-2**. Other

specific complications of peripheral and central venous access are discussed in the following chapters.

SUMMARY

Venous access is an essential skill for all providers of care to the acutely ill and injured. As with most procedures, success rates increase and complication rates decrease with experience. Successful

FIGURE 59-27. The ClearLine IV. **A.** The complete device. **B.** The inside of the device. (Photos courtesy of ClearLine MD.)

TABLE 59-2 Complications of Venous Catheterization

	Observation	Complications	Errors in technique	Response
Skin puncture site	Immediate swelling	Hematoma	Laceration or through-and-through puncture	Remove catheter, apply pressure
Skin puncture site	Delayed swelling	Extravasation or hematoma	Catheter dislodged or damaged, vein lacerated	Remove catheter, apply pressure
Skin puncture site	Erythema or discharge	Infection	Catheter in place too long, catheter or skin contaminated	Remove catheter, give parenteral antibiotics
Catheter	Cannot infuse	Thrombosis or kinking	Catheter not flushed enough, catheter not secured properly	Flush catheter, check position, remove catheter
Catheter	Blood runs up IV tubing	Arterial placement	Arterial puncture not recognized	Remove catheter, apply pressure
Catheter	Cannot aspirate from proximal lumens of multi-lumen line	Extravascular placement or migration of proximal lumens	Not enough catheter inserted; patient movement; catheter not properly secured	Change catheter over a guidewire if distal port is intravascular
Systemic	Fever	Line sepsis	Catheter left in place too long or contaminated	Remove catheter once infection is verified
Systemic	Hemodynamic or respiratory compromise	Pneumothorax, pericardial tamponade	Pleura punctured during insertion; catheter tip malpositioned	Chest radiograph, auscultate chest; pericardial or pleural drainage

venipuncture or cannulation is not the end of the Emergency Physician's obligation to the patient. Frequent reassessment of the venous access site, the equipment, and the patient is essential to prevent complications.

Heel Stick Blood Sampling

Kimberly Fugok and Christopher J. Russo

INTRODUCTION

Obtaining blood samples in newborns or infants can be a challenging task. Venous access in the patients can be difficult or limited. The vessel size and volume status of these patients can prove to be a challenge for the most skilled Emergency Physician.¹ Capillary blood sampling is the most frequently used method to obtain blood samples from infants. This chapter reviews the basic principles and techniques of heel stick blood sampling.

ANATOMY AND PATHOPHYSIOLOGY

The selection site for capillary sampling is usually based on age and weight of the patient. The heel is the most common location for capillary blood sampling because the junction between arterial and venous blood supply is located just below the dermis.² The depth of this capillary bed in newborns and infants is consistently between 0.35 and 1.6 mm and significantly increases with weight gain.³ A thick callus can form as the child ambulates and can interfere with adequate capillary blood collection at this site. Heel blood sampling is recommended in children weighing up to 10 kg. This equates to an approximate age of 6 months. Finger prick can be an alternative modality in patients over 6 months of age and weighing greater than 10 kg. The fingers or ear lobes are recommended in adults for capillary blood sampling. The third or fourth digits of the nondominant hand are the recommended site as they are less likely to have calluses. It is suggested to draw samples from the medial or lateral aspects of the heels and fingers (Figure 60-1).² These areas avoid the blood vessels, bone, nerves, and tendons.

FIGURE 60-1. The topographic anatomy of the sole of an infant's foot. The arrows represent the areas devoid of structures to perform the heel stick.

INDICATIONS

This technique is useful for small samples of blood or repeated small-volume blood samples. Commonly drawn samples include hemoglobin, hematocrit, blood glucose, and electrolytes.² This modality is ideal for premies, newborns, and infants. Heel sticks are often used up to 12 months of age. This is a source of blood when other sources (e.g., arterial lines, central venous access, and intraosseous access) are not available or appropriate.

CONTRAINDICATIONS

A heel stick is not recommended during poor peripheral perfusion or states of compromised blood flow to an extremity. Blood samples should not be collected through local infections, significant edema, or hematomas. Capillary blood gas collection is not the recommended specimen if a precise PaO₂ is needed.² Heel sticks are not the collection method of choice for blood cultures due to the likelihood of bacterial contamination.

EQUIPMENT

- Warm packs
- Latex-free gloves
- Alcohol swab
- Sterile gauze
- Capillary blood collection tubes (e.g., capillary tube microtainers)
- Incision device (**Figure 60-2**)

Heel stick incision devices and capillary blood collectors are subject to variability depending on the brand and model.² Lengths of incisions from devices vary by manufacturer. The recommended maximum depth is 2.4 mm in the heel. The devices are available in multiple sizes for different-sized patients (e.g., premies, neonates,

and infants). **Do not use a lancet.**^{4,5} A lancet has been shown to increase bruising, inflammation, the number of punctures to obtain a sufficient blood quantity, and the time required to obtain a sufficient blood quantity.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an oral informed consent for the procedure. It is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Warm the heel prior to the procedure to increase local blood flow. Apply a warm towel or a disposable single-use heating pack for approximately 5 minutes. Clean any dirt and debris from the skin. Cleanse the area with an alcohol swab (i.e., 70% isopropyl alcohol). **Allow the area to dry as the alcohol may artificially raise blood glucose levels.** Immobilize the extremity. This may be done by the Emergency Physician or an assistant to prevent the patient moving after the device is activated making blood collection more challenging. It is recommended that neonates and infants are positioned supine with the leg held in a dependent position and the heel at an 80° to 90° angle to the leg.² This position allows gravity to naturally bring blood to the heel. The patient may be held in the arms of a parent or assistant or supine on the gurney with their leg bent at the knee to attain this position. Don gloves after hand washing to prevent contamination of the patient or exposure of the Emergency Physician.

Many physicians use no anesthesia for the heel stick procedure. We know neonates and infants recognize pain from this procedure. Consider the use of heel warming, mechanical vibration, swaddling, or sweet solutions.⁶⁻¹⁰ All these have been shown to reduce the pain associated with heel sticks. Sweet solutions are shown to induce endogenous opioid mechanisms. Sweet solutions reduce crying time and pain. There are no untoward effects of the above techniques to provide analgesia.

FIGURE 60-2. (Continued)

TECHNIQUE

Remove the device from its protective wrapping. Keep the area of the blade sterile. Place the device perpendicular to the skin at the medial or lateral portion of the heel (Figures 60-1 and 60-3). **Do not pinch the heel skin, stretch the heel skin, or**

stretch the skin on the back of the leg to tighten the heel skin. These maneuvers force blood from the heel, make obtaining the sample difficult, and cause the skin puncture to be too deep. Activate the device to puncture the skin. **Avoid excessive force on the device to prevent it from puncturing too deep.**^{2,11} **Avoid squeezing or “milking” the heel.** These maneuvers may inhibit

A

B

FIGURE 60-3. The heel stick. **A.** Placement of the device. **B.** The result of a heel stick. (Photos courtesy of Accriva Diagnostics.)

capillary filling, decrease the blood flow, activate clotting, and cause hemolysis.²

Wipe away the first drop of blood with the sterile gauze. Collect the blood sample by filling the capillary blood collector to the demarcated line. **Obtaining an inadequate (i.e., too little) blood volume may produce inaccurate results.** Apply pressure to the puncture site with sterile gauze for 2 to 3 minutes to stop any bleeding. Cover the puncture site with a light adhesive dressing.

COMPLICATIONS

Capillary blood sampling has a low rate of complications. The following have been reported: hematoma, subcutaneous bruising, soft tissue infection, calcaneal puncture with osteomyelitis of the heel, scarring at the incision site, calcified nodules, nerve damage if fingers of neonates are punctured, collapse of the veins if an adjacent artery is lacerated, localized necrosis, and skin break down from repeated dressings after procedures.^{2,12-15} The choice of a proper incision device will limit uncontrolled bleeding and prevent lacerations.

There are discussions regarding the procedural pain of heel stick blood collection compared to venipuncture performed by a skilled phlebotomist. Recent studies have suggested that the heel stick procedure in newborns may cause significant discomfort, which should be taken into account.¹⁶

SUMMARY

Heel stick blood sampling is a simple, safe, and efficient way to collect blood in infants where standard blood draws may be challenging. The quickness of this procedure can obtain blood sooner than placing a central line, intraosseous line, or intravenous line.

61

Venipuncture and Peripheral Intravenous Access

Daniel Belmont

INTRODUCTION

Puncture of a peripheral vein is the most common invasive procedure performed in the Emergency Department. While some newer point-of-care testing techniques require only capillary blood, the vast majority of laboratory studies require venous blood. Cannulation of a peripheral vein is performed on a daily basis and is the cornerstone of circulatory resuscitation. It is an essential skill for all emergency personnel. A variety of approaches for obtaining peripheral venous access are described in this chapter.

ANATOMY AND PATHOPHYSIOLOGY

Veins and arteries are composed of a three-layered wall of internal endothelium, muscle, and a layer of connective tissue (**Figure 61-1**).¹ The muscular layer of a vein is much thinner and weaker than an artery. Veins can dilate and constrict in response to the pressure within them. Veins with high internal pressures become engorged and are easier to access. The use of venous tourniquets, dependent positioning, “pumping” via muscle contraction, and the local application of heat or nitroglycerin ointment all contribute to venous engorgement (Chapter 59).² These maneuvers can be used to aid in the identification of a peripheral vein.

The connective tissue surrounding veins can be a help or a hindrance during attempts at gaining peripheral venous access. Deficient connective tissue permits the vein to “roll” from side to side and evade the needle. Tough connective tissue can impede the entry of a flexible catheter through the soft tissues and into the vein. Connective tissue serves to stabilize the vein and prevent its collapse.

Venous valves are an important aspect of peripheral venous anatomy (**Figure 61-2**).¹ Venous valves encourage unidirectional flow of blood back to the heart. Gravitational forces prevent blood from pooling in the dependent portions of the extremities. Valves can impede the passage of a catheter through and into a vein. **Forcing a catheter past venous valves may damage them and contribute to later venous insufficiency.** Valves are more numerous at the points where tributaries join larger veins and in the lower extremities. Valves are almost totally absent within the large central veins and the veins of the head and neck.

Veins can be subdivided into central veins and peripheral veins. The important central veins with regard to venous access are the internal jugular, subclavian, and femoral veins. Central veins are usually larger than peripheral veins and have fewer tributaries.

Superficial peripheral veins are generally visible beneath the surface of the skin of the extremities and neck. They are often tortuous and continually merge and divide. Peripheral veins are easiest

FIGURE 61-1. Comparative anatomy of an artery and a vein. **A.** The generic blood vessel. **B.** A muscular artery. **C.** A vein. Note the vein's thinner wall with fewer myocytes and elastic fibers. This is indicative of the lower pressure within veins compared to arteries.

to access at the apex of the “Y” formed when two tributaries merge into a larger vein, where the vein is straight and free of branches for 2 cm, or more proximal to the site of puncture (**Figure 61-3**). These sites tend to be anchored and hence “roll” less than other sites. The superficial veins of the upper extremity are preferred to those of the lower extremity for peripheral venous access. Indwelling catheters in the upper extremity interfere less with patient mobility, and they pose a lower risk of phlebitis.² The superficial veins of the extremities are shown in **Figures 61-4 and 61-5**. The veins most commonly used for venipuncture and venous access are the basilic and cephalic veins as well as their branches and tributaries (**Figure 61-4**). The veins of the dorsal foot and the distal saphenous veins are the most commonly used veins in the lower extremity (**Figure 61-5**).

The depth of the vein beneath the epidermis will affect the ease with which it may be accessed. Very superficial veins are often small, fragile, and easily passed “through-and-through” with a needle resulting in a hematoma. The deeper veins are often not visible and must be located by surface landmarks, palpation, and ultrasound

(US). The angle of insertion of the needle must be varied depending on the depth of the vein being punctured (**Figure 61-6**). A shallow angle of approximately 30° to 45° should be used for small and superficial veins (**Figure 61-6A**). A more obtuse angle of 45° to 60° should be used to access deeper veins (**Figure 61-6B**). This angle allows the vein to be penetrated within a reasonable horizontal distance from the skin puncture site. Very small and very superficial veins should be entered at a very acute angle of approximately 15° to 30° (**Figure 61-6C**).

FIGURE 61-2. Venous valves. Cross section of converging veins demonstrating the valve leaflets that permit only forward flow, proximally, toward the right heart. The arrows represent the directional flow of blood.

FIGURE 61-3. Preferred vein entry points. Preferred sites (open circles) are at the apex of converging veins or in the middle of a long straight vein. Sites just distal to branching or convergence of veins (red X) are best avoided due to the presence of valves and the difficulty in threading a cannula.

FIGURE 61-4. Superficial veins of the upper extremity. **A.** Volar surface of the upper extremity. **B.** Dorsal surface of the hand and wrist.

The upper extremity is preferred to the lower for venous cannulation, and distal placement should be attempted before moving proximally.³ **Avoid veins overlying a joint if possible.** Adherence to these simple principles will allow the patient maximum mobility and increase the chance of successfully cannulating and maintaining access in the vein. **Any solutions or medications infused distally can extravasate and injure the surrounding tissues once a proximal vein has been punctured unsuccessfully.**

It is easiest to insert a venous cannula where two tributaries merge and form a “Y.” Choose a straight portion of vein without branches to minimize the chance of hitting valves within the vein. This also makes it easier to thread the catheter (**Figure 61-3**).

The deep brachial veins are variably located alongside the brachial artery, running lateral and/or medial to the artery (**Figure 61-7**).^{4,5} The brachial veins are relatively small, deep, not visible, have a

FIGURE 61-5. Superficial veins of the lower extremity. **A.** Anterior surface. **B.** Posterior surface.

close relationship to the brachial artery, and are thus not normally accessed. **It is important to prevent injury to the brachial artery when cannulating or puncturing the brachial veins.** The brachial artery is the sole arterial supply of the forearm, hand, and median nerve. The deep brachial veins may be used when superficial veins have been destroyed by scarring due to intravenous drug abuse, chemotherapy, or prior infusions. The location and cannulation of the brachial veins can be aided through the use of US.⁶

The neck is an important potential site for peripheral venous access through the external jugular vein (**Figure 61-8**). This vein begins at the level of the mandible and runs obliquely across the sternocleidomastoid muscle. It dives beneath the fascia in the subclavian triangle in the neck to join with the subclavian vein.⁵ Some patients have two external jugular veins on one or both sides as an anatomic variant. The external jugular vein has two sets of valves (**Figure 61-8**). One is located where the external jugular vein joins the subclavian vein, and the other is located approximately 4 cm above the clavicle. These valves are not fully competent but may prevent the passage of a guidewire or catheter.^{5,7}

INDICATIONS

Venous puncture (i.e., venipuncture) with a needle is indicated only for the sampling of venous blood. Medications may be administered as a one-time dose via this technique. The risk of medication extravasation with this technique is high and has fallen out of favor.

FIGURE 61-6. The angle between the needle and the skin must be varied based on the depth and diameter of the target vein. **A.** A shallow angle must be used for small and superficial veins. **B.** A steeper angle must be used for deeper veins. **C.** A butterfly-type needle permits the shallowest angle of entry for very small and superficial veins.

Venous cannulation is indicated for sampling of venous blood. It is also performed for the administration of intravenous medications, fluid solutions, blood products, and partial nutritional support. Full nutritional support requires central venous access. The specific indications for peripheral venous access, central venous access, and the various techniques of venous cannulation are discussed below and in Chapters 60 through 64.

CONTRAINDICATIONS

Sclerosing solutions, vasopressors, concentrated solutions of electrolytes or glucose, and chemotherapeutic agents are more safely infused into a central vein. Avoid peripheral venous access in an injured extremity to not interfere with care of the injury and venous drainage of the limb. Do not perform intravenous cannulation and venipuncture through infected or burned skin if possible.

Do not use a vein proximal to a running venous infusion for venous blood sampling. The blood sample will be tainted or diluted

by the infused solution. The hole in the vein may allow blood, infused solutions, and medications to extravasate into the surrounding tissues.

Avoid venipuncture and venous cannulation in an extremity with an arteriovenous fistula. Do not puncture veins in the upper extremity that may be needed for arteriovenous fistula construction for hemodialysis in the near future unless absolutely necessary. Scarring of the vein may complicate later surgical procedures.

EQUIPMENT

- Alcohol swabs
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution
- 25 gauge needle
- 1 mL syringe
- Gloves
- Immobilization supplies, if necessary
- 1 inch tape, waterproof or plastic
- Transparent dressing
- Gauze 4×4 squares
- Tourniquet
- Desired venous access device
- Saline lock or infusion set
- Intravenous fluids
- Vacuum blood collection tubes
- Medicine cup
- Scissors
- Gauze roll or stockinette

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. Obtain verbal consent for the venipuncture unless it is an emergency. Select a site for the venipuncture. A site in the upper extremity is preferred. While a satisfactory vein is usually evident upon inspection, the placement of a venous tourniquet will aid the process greatly. It is easiest to place the tourniquet a few inches proximal to the elbow when first trying to locate a vein in the upper extremity. This restricts venous return from the entire extremity distal to the tourniquet and allows rapid inspection of the entire limb. Release the tourniquet once the site is chosen.

The use of dependent positioning, “pumping” via muscle contraction, and the local application of heat or nitroglycerin ointment will all contribute to venous engorgement if difficulty is encountered in finding a vein (Chapter 59).² These maneuvers can be used to aid in the performance of a venipuncture or peripheral venous access. A device specifically designed to identify veins may also be used (Chapter 59).

Clean the puncture site of any dirt and debris. Apply an alcohol swab, povidone iodine solution, or chlorhexidine solution to the area overlying the identified vein and allow it to dry.⁸ Wipe off the povidone iodine with an alcohol swab after it dries to lessen the chance of a local skin reaction. Infiltrate a small amount of local anesthetic solution subcutaneously with a 25 gauge needle over the puncture site. **Take care not to puncture the target vein**

FIGURE 61-7. The deep brachial veins. **A.** The deep brachial veins are located deep to the biceps tendon and muscle, and adjacent to the brachial artery. **B.** Cross section of the arm 2 cm above the elbow. Note the two deep brachial veins, one on each side of the brachial artery.

FIGURE 61-8. The external jugular veins. The anterior external jugular vein is usually larger than the posterior and runs deep to the platysma muscle. Note its relationship to the internal jugular vein. Valves (noted by the X) are normally present in the external jugular vein where it enters the subclavian vein and approximately 4 cm superior to the clavicle.

accidentally. Other methods of anesthesia are available and do not cause pain (Chapter 154). Reapply the tourniquet.

TECHNIQUES

PERIPHERAL VENIPUNCTURE

Stabilize the vein with the nondominant hand (**Figure 61-9**). Insert the needle attached to a syringe or vacuum tube adapter with the bevel upward and into the vein at a 30° to 45° angle (**Figure 61-6A**).⁹ Lower angles, at times nearly parallel to the skin, may be needed to enter very narrow or superficial veins. This is easiest to achieve with a butterfly-type needle (**Figure 61-6C**). Apply negative pressure to the syringe. A flashback of blood in the hub of the needle indicates that the tip of the needle is within the vein. Pulsatile blood that pushes back the syringe plunger indicates an arterial puncture. **Collect the necessary samples before removing the intraarterial needle unless venous blood is specifically needed for a test.** No additional harm will be done by withdrawing a blood sample from an artery that has already been punctured.

Slowly advance the needle until it is deeper than the judged depth of the vein if no blood is obtained. Apply negative pressure to the syringe and slowly withdraw the needle. The vein will often have been punctured through-and-through (**Figure 61-10B**), and the specimen will be obtained as the needle is withdrawn (**Figure 61-10C**). Redirect the needle and make another attempt at puncturing the vein if no blood is obtained by the time the needle is withdrawn to just beneath the skin. **Never sweep the point of the needle around without withdrawing it as the sharp bevel of the needle can lacerate nearby structures.** Remove the tourniquet and apply direct pressure for several minutes if swelling develops indicating a hematoma formation. Search for another venous access site. Accidental peripheral arterial punctures should have direct pressure applied for at least 5 minutes.

The Touch Activated Phlebotomy or TAP device (Seventh Sense Biosystems, Medford, MA) was developed for venipuncture (**Figure 59-17**). The base of the device uses adhesive to stick and form an airtight seal on the skin of the upper arm. Pushing the button on the top of the device activates 30 thin needles that penetrate the skin. This micropuncture causes no pain, takes 2 minutes, and obtains 100 µL of blood. Blood is collected in a reservoir with anticoagulant. The device has an indicator for when the blood collection is complete. The laboratory can extract the sample from the TAP device and analyze the blood using regular methods.

FIGURE 61-10. Through-and-through puncture of the vein. **A.** The tip of the hypodermic needle can collapse the vein and prevents a flashback of blood in the syringe. **B.** The vein may be punctured through-and-through. **C.** Slow withdrawal of the needle permits the vein to open and blood to return into the syringe.

FIGURE 61-9. Stabilization of the vein during venipuncture. **A.** The vein may kink or roll away from the tip of the hypodermic needle without stabilization. **B.** Gentle stabilizing pressure applied with the fingertips allows entry into the vein. **C.** The nondominant thumb is used to stabilize the skin.

FIGURE 61-11. The catheter-over-the-needle technique. **A.** The vein is punctured and blood returns in the needle hub. **B.** The catheter is advanced over the needle and into the vein. **C.** The needle is removed.

PERIPHERAL INTRAVENOUS CANNULATION

Cannulation of a vein begins with a successful venipuncture with the desired device, as described above. This section focuses on the use of the catheter-over-the-needle technique of peripheral venous access. This is the most commonly used method for venous cannulation.

Insert the catheter-over-the-needle bevel upward through the skin and into the vein (**Figure 61-11A**).⁹ A flash of blood in the hub of the needle confirms that the tip of the needle is within the vein. Advance the catheter-over-the-needle an additional 2 to 3 mm to ensure that the catheter is within the vein. An alternative is to drop the hub of the needle nearly parallel to the skin before advancing the catheter-over-the-needle (**Figure 61-12A**). This will prevent the needle from puncturing the far wall of the vein (**Figure 61-12B**) and the catheter from pushing the vein away from the needle (**Figure 61-12C**). Hold the hub of the needle securely. Advance the catheter over the needle until its hub is against the skin (**Figure 61-11B**). Securely hold the hub of the catheter against the skin. Withdraw the needle (**Figure 61-11C**). Apply pressure with the nondominant index finger over the skin above the catheter to prevent blood from exiting the catheter (**Figure 61-13A**).

FIGURE 61-12. Advancing the catheter-over-the-needle. **A.** Drop the catheter hub toward the skin and then advance the catheter-over-the-needle 2 to 3 mm into the vein. **B.** The far wall of the vein may be punctured if the needle is advanced at the original angle to the skin. **C.** The catheter may push the vein off the end of the needle if the catheter is advanced over the needle as soon as the vein is entered.

Apply a device or intravenous tubing to the hub of the catheter while applying digital pressure over the catheter. A syringe or vacuum device may be attached to the catheter to draw blood samples (**Figure 61-13B**). Intravenous tubing can be attached to the catheter to begin a fluid infusion (**Figure 61-13C**). A saline lock may be attached to the catheter to be used later for intravenous access (**Figure 61-13D**). Remove the tourniquet.

Secure the intravenous catheter to the skin (**Figure 61-14**). There are numerous methods to tape the catheter to the skin, but only two are described here. Place a 2 inch piece of adhesive tape sticky side up under the catheter hub (**Figure 61-14A**). Fold the ends of the adhesive tape over the catheter and onto the skin to form a “chevron” (**Figure 61-14B**) or a “U” (**Figure 61-14C**). Apply a 2 inch piece of adhesive tape over the catheter hub (**Figure 61-14D**). Place a transparent dressing over the catheter hub and distal intravenous tubing (**Figure 61-14E**). Some prefer to use the transparent dressing without the adhesive tape. The catheter may be sutured to the

FIGURE 61-13. Peripheral intravenous cannulation. **A.** Apply gentle pressure over the catheter with a gloved finger to prevent hemorrhage from the catheter hub. **B.** Blood samples may be withdrawn from the cannula via syringe or vacuum tubes. **C.** Intravenous infusion tubing is attached to the catheter. **D.** A saline lock is attached to the catheter.

skin when vascular access is essential and when the catheter may be pulled out by a young child or combative patient. It is very rare that a peripheral intravenous catheter must be sewn into place.

ALTERNATIVE TECHNIQUES

ARTERIAL LINE KIT

The modified Seldinger technique with a QuickFlash radial artery catheterization set (Arrow International, Bloomington, IN) is very useful for the catheterization of deep brachial and external jugular veins. The unit is commonly available in Emergency Departments and Intensive Care Units. It consists of a one-piece unit that incorporates a catheter-over-the-needle, a guidewire in a feed tube, and a lever to advance the guidewire (Figure 61-15). The black mark on the feed tube is a reference mark. The tip of the guidewire is positioned at the tip of the needle when the advancement lever is at the reference mark. The unit is also available without the catheter-over-the-needle as the Positive Placement Spring-Wire Guide (Arrow International, Bloomington, IN). It can be attached to a standard stock catheter-over-the-needle. A similar device is The WAND (Access Scientific, San Diego, CA).

The integral guidewire and soft, 2 inch long, 20 gauge catheter found in the QuickFlash set can ease the process of catheterization considerably. The depth of the deep brachial vein combined with overlying skin that is often scarred from previous venipunctures makes catheterization with the usual 1¼ inch catheter difficult. The

external jugular vein is quite mobile, and the overlying tissues are fairly tough. This can make it quite difficult to thread an over-the-needle-catheter into the vein without pushing the vein off the end of the needle.

Select a vein to cannulate. Clean and prep the skin overlying the puncture site. Place a tourniquet on the extremity. Open the package and remove the unit. Advance the guidewire through the needle and then retract it. Do not use the catheterization unit if the guidewire does not advance and retract smoothly. Ensure that the guidewire advancement lever is retracted as far as possible so that the guidewire is not within the needle. **The flashback of blood will not be seen if the guidewire is not fully retracted and out of the needle.**

Stabilize the vein with the nondominant hand. Insert the catheter-over-the-needle with the bevel upward through the skin and into the vein (Figure 61-16A).⁹ A flash of blood in the hub of the needle indicates that the tip of the needle is within the vein. Hold the needle hub securely. Advance the guidewire, using the advancement lever, into the vein (Figure 61-16B). Continue to advance the guidewire as far as possible into the vein. **The advancement lever must be distal to the reference mark to ensure that the guidewire is past the tip of the needle. Stop advancing the guidewire if resistance is encountered. Do not force the guidewire against resistance. Do not retract the guidewire if resistance to advancement is encountered. Doing so may damage the vein or shear off a piece of the guidewire. Withdraw the entire unit and repeat the procedure with a new unit.**

FIGURE 61-14. Securing the intravenous catheter. **A.** Place a narrow strip of adhesive tape sticky side up under the catheter hub. **B.** Fold the tape over the catheter to form a “chevron.” **C.** Alternatively, the tape with the sticky side up can be folded to form a “U.” **D.** A second piece of tape is applied to better secure the catheter to the skin. **E.** A transparent dressing is applied over the catheter.

Advance the guidewire as far as possible into the vein. Advance the catheter-over-the-needle an additional 1 to 2 mm into the vein. This will ensure that the tip of the catheter is within the vein. Hold the hub of the needle securely. Advance the catheter over the needle and guidewire until its hub is against the skin (**Figure 61-16C**). A twisting motion may help to advance the catheter against resistance. Release the tourniquet. Hold the catheter hub firmly against the skin. Remove the needle and guidewire, through the catheter, as a

FIGURE 61-15. The Arrow QuickFlash radial artery catheterization set. Note the different positions of the guidewire. The guidewire is within the feed tube (*top*). The tip of the guidewire is at the tip of the needle when the advancement lever is at the reference mark (*middle*). The guidewire is advanced through the catheter-over-the-needle (*bottom*).

unit. Attach a syringe, vacuum blood collection system, intravenous line, or saline lock onto the catheter hub. Secure the catheter with adhesive tape.

EXTERNAL JUGULAR VEIN CANNULATION

Place the patient in the Trendelenburg position to distend the external jugular vein (**Figure 61-17**). Turn the patient's head to the opposite side. This will gently stretch the vein and prevent it from rolling. Do not overturn the patient's head and compress the external jugular vein. Clean and prep the skin of the neck. Place the nondominant thumb or index finger above the midportion of the clavicle to obstruct outflow and distend the external jugular vein. Align the catheter-over-the-needle parallel to the vein with the bevel of the needle upward and the tip of the needle pointing toward the clavicle (**Figure 61-17**).⁹ Enter the vein midway between the angle of the mandible and the mid-clavicle. Insert the catheter-over-the-needle during inspiration when the valves of the external jugular vein are open. **Be sure to cover the open hub of the needle and/or catheter**

FIGURE 61-16. The Arrow QuickFlash radial artery catheterization set. **A.** The vein is punctured and blood returns into the hub of the needle. **B.** The guidewire is advanced into the vein. **C.** The catheter is advanced over the needle and guidewire with a back-and-forth rotating motion. The needle and guidewire are then removed as a unit.

with a finger at all times to prevent an air embolism. Attempt to insert the catheter-over-the-needle obliquely into the vein if it rolls when trying to access it. Another option is to cannulate the vein in the area where a tributary joins it. These areas are often anchored in the subcutaneous tissue. The remainder of the technique is similar to that described previously.

FIGURE 61-17. External jugular vein cannulation.

DEEP BRACHIAL VEIN CANNULATION

Extend the patient's arm. Identify the brachial artery pulse by palpation or US in the antecubital fossa. Clean and prep the skin of the antecubital fossa. Place a tourniquet on the upper arm. Reidentify the brachial artery pulse. Place a 2 to 3 inch long catheter-over-the-needle onto a 5 mL syringe and insert it bevel upward just medial or lateral to the brachial artery pulse and at a 30° to 45° angle to the skin with the tip of the needle pointing cephalad.⁹ Advance the catheter-over-the-needle while applying negative pressure to the syringe. A flash of blood in the syringe indicates that the vein has been entered. Slowly withdraw the catheter-over-the-needle if a flash is not seen. It may have gone "through-and-through." A flash will be seen as the catheter-over-the-needle is withdrawn and the tip of the needle reenters the vein. The remainder of the technique is similar to that described previously. The use of US can significantly improve the success rate of deep brachial vein cannulation (**Figure 61-18**). Complications include brachial artery puncture, clotting of the brachial artery, hand ischemia, hematoma formation, loss of vascular access, and transient paresthesias.^{3,10}

ULTRASOUND-GUIDED PERIPHERAL VEIN CANNULATION

A deep peripheral vein, often the brachial or basilic vein, may be cannulated under direct visualization using ultrasonography (**Figure 61-18**).³ US may be used to identify a superficial vein when one is not palpable or visible. Place a tourniquet on the upper arm. Identify the vein by placing the US transducer perpendicular to the vein. Identify the vein as a thin-walled, nonpulsatile, vascular structure. Move the US transducer along the vein to identify its most superficial and easiest accessed point. Insert the catheter-over-the-needle under direct visualization.^{11,12}

The easiest way to gage the depth of the vein is to note its depth on the US screen. Move the US transducer distally this same distance while still maintaining visualization of the vein. Insert the catheter-over-the-needle at a 45° angle and advance it until the tip of the needle is seen on the US screen. Puncture the vein wall using a quick and short jabbing motion. Take care to not puncture through the posterior wall of the vein. Once the tip of the needle is seen within the vein, advance the catheter-over-the-needle and into the vein. Refer to Chapter 64 for the complete details of US-guided vascular access.

PEDIATRIC CONSIDERATIONS

Venipuncture and peripheral venous access can be quite a challenge in the infant, neonate, and small child. Proper restraint of the extremity with a board or an assistant will greatly aid the process. Aside from the techniques discussed above, there are a few techniques that can facilitate pediatric vascular access.^{13,14} The scalp veins can be used for venous access in newborns, infants,

FIGURE 61-20. Cannulation of a small superficial vein with a catheter-over-the-needle. **A.** The “shoulder” of the catheter hub prevents the needle from being placed nearly parallel to the skin. **B.** A slight bend at the base of the needle permits the needle to run nearly parallel to the skin surface, enabling the subcutaneous vein to be cannulated. Always make sure that the catheter can be advanced over the needle before puncturing the patient’s skin.

and children up to 1 year of age (**Figure 61-19**). They are most easily cannulated with a small (i.e., 23 or 25 gauge) butterfly needle or catheter. Place a rubber band around the baby’s head as a tourniquet (**Figure 61-19**). Other veins commonly used include those of the antecubital fossa, dorsal hand, dorsal foot, external jugular vein, and saphenous vein at the knee or groin.¹⁵ It can be helpful to place a small bend at the hub of the catheter-over-the-needle assembly for small and superficial veins (**Figure 61-20**).

FIGURE 61-19. Scalp vein cannulation in the neonate. A rubber band makes a convenient tourniquet.

This allows for the use of a less acute angle and easier entry into the vein without puncturing the far wall.

The best guide to the gauge (i.e., diameter) of catheter to use is to compare the catheter to the vein. The catheter should be slightly smaller than the vein. The smallest readily available catheters are usually 24 gauge. A 22 gauge catheter will allow a much higher flow rate if it can be inserted successfully.

Keeping a peripheral intravenous line from being pulled out by an active child is quite a challenge. Each institution has its own “recipe” for securing pediatric intravenous lines. The catheter is secured to the skin in the usual manner (Figure 61-14). Several strips of tape can be placed to secure the intravenous tubing to the skin and act as “strain reliefs” to prevent traction applied to the intravenous tubing from being transmitted to the catheter. Half of a medicine cup can be used as a shield for the catheter (Figure 61-21A). Apply tape over the cut edges of the cup to prevent the sharp edges from cutting the child’s delicate skin. The clear medicine cup acts as a window so the catheterization site can easily be inspected without removing all the dressings. The whole assembly, or just the taped intravenous line, can then be covered with a gauze roll or stockinette (Figure 61-21B). A cup with one-quarter or one-third cut away may be used to protect a scalp vein access site (Figure 61-21C). A splint applied to the extremity will increase the duration of intravenous line patency.¹⁶

ASSESSMENT

The intravenous line should flush easily. Any infusions should flow by gravity alone. Progressive swelling at the catheterization site indicates the formation of a hematoma or extravasation of infused fluids. Peripheral infusions of vasopressors and caustic solutions require the skin puncture site to be assessed frequently and carefully, since extravasation may lead to extensive local soft tissue necrosis. Pain at the intravenous access site must be taken seriously and should prompt a search for the cause. Pinched skin, extravasation, or thrombosis must be looked for and ruled out.

AFTERCARE

The intravenous (IV) catheter needs to be secured. The use of tissue adhesive at the skin puncture site can prevent the catheter from moving. The tissue adhesive prevents dislodgement, infection, occlusion, and phlebitis.¹⁷ Removal may be problematic. Cover the IV and skin puncture site with a clear dressing.¹⁸ Tegaderm dressings are most often used because of convenience. Special clear dressings with cutouts are available (Figure 59-23). These come in a variety of sizes and cost more than a Tegaderm.

Most authorities recommend changing peripheral infusion sites at least every 3 days, although this is probably overly cautious.^{19,20} It may be impractical if the patient has poor superficial veins. Any cannula with signs of venous thrombosis, skin erythema, or puncture site discharge must be removed at once. Heparin or saline locks that have not been accessed should be flushed regularly, usually every 8 hours. Saline works as well as heparin solutions for most applications.²¹ Approximately 1 to 2 mL of sterile saline to flush is adequate for peripheral venous catheters. Heparin flushed cannulations have an increase in duration of patency.¹³

Dressings should be inspected and changed if they have become moist or contaminated. Routine dressing changes are probably unnecessary.²¹ Transparent dressings are widely used despite some studies suggesting that transparent occlusive dressings are associated with higher rates of infection than plain gauze dressings.¹⁰ Transparent dressings have the advantages of allowing easy inspection of the catheter site and holding the catheter securely in place. Individual institutions often have their own nursing guidelines and infection control statistics to support their choice of dressing.

FIGURE 61-21. Securing pediatric intravenous lines. **A.** Use a clear plastic medicine cup, cut in half lengthwise, to protect the skin puncture site. **B.** A stockinette or gauze roll can be used to further protect the site from manipulation. **C.** Protecting a scalp vein cannula with tape and a clear plastic medicine cup.

The IV Pro (WV IV Pro Inc., Fairmont, WV) can be applied (Figure 59-24). This shield was designed to protect the IV site from buildup of bacteria and needle dislodgement. It is a protector and securement device and not a dressing. The clear dome allows site monitoring. Its holes allow airflow and prevent condensation. The device can be used multiple times in the same patient.

Other devices may be added for patient safety. The ivWatch (ivWatch, Williamsburg, VA) monitors the IV site to detect leaks, extravasation, and infiltration (Figure 59-25). It is composed of the patient monitor, a reusable sensor cable, single-use disposable sensor applied next to the IV site, and an AC adapter. The monitor gives an audible and visual alert. The FIVA (FIVAMed Inc., Halifax, Canada) attaches in-line and alerts to the empty IV fluid bag

(Figure 59-26).²² The FIVA clips onto the IV line and uses infrared to detect air bubbles in the IV tubing and stop the flow. The FIVA gives an audible and visual alert. It is meant to be used for gravity drips and pressure bags and not pumps. Currently, the device is only approved for use in Canada. The ClearLine (ClearLine MD, Woburn, MA) prevents air bubbles in the IV tubing from entering the patient (Figure 59-27). The device uses US to monitor the IV tubing for air bubbles as small as 25 μm . The bubbles are directed into a disposable bag. The device works with gravity drips, pumps, and fluid warmers.

REMOVAL OF INTRAVENOUS CATHETERS

Turn off any IV infusions and clamp the tubing. Place the infusion site in a dependent position below the right atrium to prevent a venous air embolism. Remove any tape and dressings from the infusion site. Apply direct pressure to the skin puncture site with a gauze pad. Briskly remove the catheter or needle. Hold firm direct pressure for several minutes. Apply a bandage. Instruct the patient to check for signs of thrombophlebitis, cellulitis, and an infection for the next several days.

COMPLICATIONS

PERIPHERAL VENIPUNCTURE

The main complications of venipuncture are pain and hematoma formation. Minimize pain during venipuncture by using small gauge needles, clearly identifying a vein before attempts at venipuncture, and minimizing the number of attempts at venipuncture. Prevent hematomas and bleeding by removing the tourniquet before removing the needle and applying direct pressure after the needle is removed. Hematomas are self-limited and easily treated with nonsteroidal anti-inflammatory drugs, cool compresses for analgesia, and warm compresses to hasten hematoma resorption. Other complications include nerve injury, usually reversible paresthesias. Arterial puncture is common with deep brachial lines and may rarely be catastrophic if it causes thrombosis of the brachial artery, the sole arterial supply of the forearm and hand.¹⁰ Infection from simple venipuncture is uncommon.

PERIPHERAL INTRAVENOUS CANNULATION

In addition to the complications described for venipuncture, indwelling venous catheters pose additional risks (Table 59-2). The steel needle cannula of the butterfly needle can move easily and cause lacerations of the vein and neighboring structures. The risk of infection is greater the longer a catheter is left in place. IV catheters increase the risk of superficial venous thrombosis and thrombophlebitis. This may be prevented by limiting catheter manipulation during tubing changes and by using extension tubing at the catheter hub. Complications are more common when the intravenous catheter is placed in the hand or forearm when compared to other sites.²³ This may be the result of the higher frequency of catheters placed in these two sites in this small study. It is possible to injure a number of structures in the neck during external jugular vein cannulation. This includes the carotid artery, internal jugular vein, and trachea. It is also possible to cause a pneumothorax. Avoid deep penetration with the needle to prevent these complications.

Extravasation of vasopressors or caustic solutions can cause local skin necrosis (Chapter 141). Extravasation of large volumes into a muscle compartment can lead to a compartment syndrome (Chapter 93). This is rare with superficial peripheral venous lines. Prevent extravasation and tissue injury by using a small gauge

catheter in a large vein, diluting medications before administration, and observing IV access sites frequently.

Infections can often be prevented by using aseptic technique and sterile dressings and changing peripheral catheters every 48 to 72 hours. The complications of peripheral nerve palsies, pressure necrosis, and compromised peripheral circulation are rare but do occasionally occur. Prevent these with frequent neurovascular checks to any restrained extremity, by padding all pressure points, and by avoiding the placement of circumferential tape on an extremity.

SUMMARY

Venipuncture and peripheral venous access are essential skills for nearly all medical practitioners. The only way to become proficient at these techniques is to master them during training and to practice them regularly. Equally important is frequent reassessment of venous cannulas so that complications can be detected and treated early before they become major problems.

Peripheral Inserted Central Catheter (PICC) Lines

Elizabeth Barrall Werley

INTRODUCTION

There are a variety of short-, moderate-, and long-term vascular access devices available (i.e., midline catheters, nontunneled central venous catheters, peripheral inserted central catheters [PICCs], peripheral intravenous [IV] catheters, ports, tunneled central venous catheters, and ultrasound [US]-guided peripheral IV catheters). PICC lines are commonly used in adults and children.¹⁻³ PICC lines provide options that routine peripheral IV access or other devices do not provide and without the risks associated with direct puncture of central vessels.⁴ PICC lines are a cost-effective option that can often be inserted at the bedside.^{5,6} A PICC line reduces health care costs by permitting the patient to receive care as an outpatient.^{7,8}

The insertion of a PICC line is infrequently performed in the Emergency Department (ED) and rarely by an Emergency Physician (EP). A PICC line is inserted more commonly by an Interventional Radiologist and their team or a skilled nursing team dedicated to placing PICC lines. An EP may request PICC line placement for a patient given the appropriate clinical scenario. Patients with indwelling PICC lines may present to an ED with complications associated with the PICC line. **Be prepared to recognize the device, determine its use and functionality, and troubleshoot any potential complications.**

ANATOMY AND PATHOPHYSIOLOGY

The veins of the upper extremities are the typical sites for PICC lines to be placed (Figures 61-3 and 61-4). The vessels most frequently used are the basilic, brachial, and cephalic veins proximal to the antecubital fossa to avoid occlusion or damage caused by elbow flexion.⁹⁻¹² Rarely, the axillary vein, scalp veins, superior vena cava (SVC), a transhepatic approach, or a translumbar approach may be used.¹³⁻¹⁵ The veins may be accessed by palpation or some form of diagnostic imaging to guide vein selection. US is often used prior to PICC line placement to determine the patency and size of the veins potentially being accessed (Figure 62-1). US use decreases the time needed for insertion, decreases PICC line manipulation, and decreases the need for ionizing radiation when compared to standard blind landmark or blind length techniques.¹⁶ A tourniquet may be used to impede venous return and make the target veins more dilated.⁹ Contrast venography of the upper extremity performed under fluoroscopy may be used to select the target vessels. This requires peripheral IV access in a distal superficial vein of the arm and injection of venous contrast to opacify the vessels during fluoroscopy. A tourniquet for venous dilatation will enhance opacification of the vessels.⁹

FIGURE 62-1. Transverse ultrasound image of the veins proximal to the antecubital fossa in the right upper extremity. BrA, brachial artery; BrV, brachial vein; BV, basilic vein. (Courtesy of Mark R. Werley, MD.)

PICC LINES VERSUS MIDLINE CATHETERS

Physicians are using midline catheters more frequently for venous vascular access.¹⁷ The main differences are how far the catheter is inserted (Figure 62-2). The midline catheter is much shorter and does not require radiography to confirm it is in the proper location and not inserted too far. The midline catheter has its tip positioned at or below the axillary vein. It does not dwell in the central circulation like a PICC line or central line. There are numerous similarities between these two types of catheters. They are inserted in the same location. Both are available in a variety of lengths and lumens. Both are available in power injection models. The indications, contraindications, and insertion are similar. US can be used to insert the catheters. The literature primarily compares midline catheters to peripheral IVs and central lines. The use of midline catheters may eventually be used in the ED.

INDICATIONS

Some indications for PICC lines are clearer than others. The duration and type of treatment impact the decision to use a PICC line. A multispecialty panel used the RAND Corporation/University of California Los Angeles (RAND/UCLA) Appropriateness Method to develop criteria for appropriate use of PICC lines and other venous access devices.⁴ The Michigan Appropriateness Guide for Intravenous Catheters (MAGIC) is one of the most comprehensive reviews of the literature combined with expert opinion.⁴ Irritant or vesicant infusions (e.g., chemotherapy or total parenteral nutrition [TPN]) are incompatible with peripheral veins. This is deemed an appropriate indication for a PICC line regardless of the proposed duration of treatment. The risk of thrombosis needs to be considered in patients with active malignancy or prior clotting history.¹⁸ A summary of the indications for PICC lines according to the MAGIC guidelines can be found in Table 62-1.

PICC lines have the advantages of decreased cost, increased durability, lower infection rates, and outpatient or bedside insertion/removal when compared to other venous access devices. The PICC line is easier to maintain than other venous access devices. The procedure only requires local anesthesia and no procedural sedation or general anesthesia.^{7,8,12} This is beneficial in some high-risk patient populations.^{7,8,12} Newer PICC lines often tolerate higher flow rates, permit hemodynamic monitoring, and allow

FIGURE 62-2. The different placement of the PICC line and the midline catheter. (Used from www.commonswikimedia.org.)

for the power injection of contrast material for computed tomography (CT) imaging. Power injectable PICC lines negate the need for larger-bore peripheral IV access to accommodate the power injection of IV contrast.^{19,20} Power injectable PICC lines tolerate contrast injection rates up to 5 mL per second and up to 300 psi (**Figure 62-3**). This allows studies that may have otherwise been cancelled or performed without IV contrast. PICC lines are particularly advantageous in the chronically ill, especially the pediatric population. Multiple repeated peripheral IV catheter attempts are not required for access or blood sampling.

PICC lines are used to administer parenteral antimicrobial therapy in the outpatient setting (e.g., private homes or skilled nursing facilities).² These patients no longer need inpatient monitoring and treatment but require prolonged courses of IV antimicrobial therapy. PICC lines are the most convenient option to administer concentrated parenteral antimicrobials due to their central location.⁷ Outpatient parenteral antimicrobial therapy is used for bacteremia, bone infections (i.e., osteomyelitis), endocarditis, joint infections, skin infections, and soft tissue infections. There is increasing use of PICC lines for device

infections, intraabdominal infections, line infections, and prosthesis infections.⁷

PICC lines are commonly used in patients with active malignancy. They can be used to administer IV chemotherapy. The PICC line provides the benefits of administration of antimicrobial therapy, administration of blood products, easy blood draws, fluid hydration, palliative medications, and parenteral nutrition.^{8,12,21}

CONTRAINDICATIONS

The MAGIC guidelines do not address the contraindications to PICC placement. They discuss the consensus agreement on inappropriate indications for PICC lines.⁴ Examples of inappropriate indications include any infusion of substances other than those incompatible with peripheral veins or infrequent blood sampling if less than 6 days. A PICC line is not considered appropriate if chemotherapeutic agents are compatible with a peripheral vein and estimated to be administered cyclically for less than 3 months. The request for patient comfort if the patient is not under hospice care or actively dying is considered inappropriate. A PICC line is considered inappropriate for an infusion that is compatible with a peripheral vein and the duration of treatment is “short” or in a hemodynamically unstable patient who requires central venous access. Other contraindications to PICC line placement include an overlying skin or soft tissue infection at the intended insertion site, impaired venous return (e.g., lymphedema or previous axillary node dissection), and thrombophlebitis.²²

A PICC line is not appropriate for patients with advanced kidney disease or those already receiving renal replacement therapy. It is advised to preserve the veins of the upper extremities for future dialysis access sites whenever possible.^{4,9} Alternate sites (e.g., neck veins) or alternate venous access devices may need to be considered.¹⁰

PICC lines may not be the ideal venous access device in the critical care setting. Volume resuscitation is not always feasible due to lower flow rates and higher resistance from the dimensions of the catheter lumens. Many PICC lines have only a single or double lumen. This does not provide enough options for the multiple infusions critically ill patients often receive.¹⁴

There are socioeconomic issues to consider. PICC line placement is unlikely to be a good option if the patient lives alone or without access to assistance, if the patient is without communication, if the patient lives in isolated areas, if there is a language barrier that cannot be overcome by translators or family, or if the patients are aggressive, do not cope well when ill, or are active substance abusers.⁷ Consider placement in a skilled nursing facility for treatment with indwelling vascular access methods.

TABLE 62-1 Summary of Appropriate Indications for PICCs

Situation	Proposed duration
Peripherally compatible infusate	<ul style="list-style-type: none"> If ≥ 6 days up to 14 days, a midline catheter or ultrasound-guided peripheral IV catheter is preferred, but a PICC line is considered an appropriate option If > 15 days, a PICC line is preferred.
Non-peripherally compatible infusate	Indicated regardless of proposed duration.
Peripherally compatible cyclical/episodic chemotherapy	<ul style="list-style-type: none"> ≥ 3 months. The risk of thrombosis must be considered.
Central venous access/invasive hemodynamic monitoring (critically ill)	<ul style="list-style-type: none"> ≥ 15 days. If < 14 days or urgent venous access is needed, a non-tunneled central venous catheter is preferred.
Frequent phlebotomy (inpatient)	≥ 6 days.
Intermittent infusions/infrequent phlebotomy (patients with poor peripheral IV access)	<ul style="list-style-type: none"> ≥ 6 days. A midline catheter or ultrasound-guided peripheral IV catheter is preferred.
Infusions/palliative treatment during end-of-life care	PICC line considered appropriate if it facilitates end-of-life goals.
Peripherally compatible infusions (residents of skilled nursing facilities or transitioning from inpatient to home)	≥ 15 days.

Source: Adapted from reference 4.

FIGURE 62-3. Power injectable PICCs. Lumens are labeled individually if they support power injection. Clamps showing a flow rate of 5 mL/sec also signify compatibility with power injection. (Courtesy of Joshua Kamnetz, MD.)

EQUIPMENT

- Distal peripheral IV catheter on arm to be accessed if using venography
- Fluoroscopy unit
- Syringes prefilled with nonionic contrast
- US machine
- US vascular transducer
- Sterile US transducer cover
- Sterile US gel
- US needle guide, optional
- Arm board for children
- Tourniquet
- Povidone iodine or chlorhexidine solution
- Hat
- Mask
- Sterile gown
- Sterile gloves
- Local anesthetic solution
- 21 gauge micropuncture needle
- #11 scalpel
- PICC guidewire, catheter, and peel-away sheath
- Needleless catheter caps
- Syringes for aspiration
- Saline flushes
- Heparin locking solution
- Suture material or adhesive dressing

PICC access kits are commercially available and include all the required supplies (**Figure 62-4A**). PICC lines are typically made of polyurethane or silicone, measure 50 to 60 cm in length, and vary from 2 to 7 French (**Figures 62-4A through 62-4D**).^{10,15,23} The PICC line is inserted through a peel-away sheath (**Figure 62-4C**). The catheter will usually need its length trimmed (**Figure 62-4D**). This is done via external measurements prior to obtaining venous access or by measuring with an intravascular guidewire placed after obtaining venous access. A good external estimate is to measure from the intended entry site, along the arm to the midclavicular line, and then down to the third intercostal space.²¹ The goal for the catheter tip is the high right atrium, the lower third of the SVC, or the junction of the SVC and right atrium (**Figure 62-5**).^{10,21-23} Caution needs to be maintained regarding positioning. The ultimate location of the catheter tip may change from when the

catheter is placed in the abducted arm with the patient supine to when the patient stands.^{6,10}

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

The procedure for PICC line placement can be done at the bedside by specially trained nurses with US guidance or other localization techniques. Placement by a physician in a procedure suite is indicated if this option is not available or unsuccessful.^{6,11,24}

PICC line insertion is considered a lower risk procedure compared to the insertion of other vascular access devices. Preprocedure laboratory values are not required. It may be helpful to know the patient's baseline coagulation profile, hemoglobin, and platelet count on a case-by-case basis. It is advisable to obtain the patient's renal function if contrast will be used for venography.²¹

Prepare for the procedure. Place the procedural access arm, ideally the nondominant arm, abducted with the palm facing up. Identify the target vein on the arm by palpation or US. Clean the area of any blood, debris, and dirt. Apply chlorhexidine or povidone iodine to the area and let it dry. **Maintain sterility from this point forward.** Don full personal protective equipment (i.e., hat, mask, sterile gloves, and sterile gown). This protects from exposure to the patient's blood and the patient from iatrogenic infections. Apply sterile drapes onto the patient to demarcate a sterile field.

Prepare the US transducer if using US with the procedure. Have an assistant apply US gel over the footprint of the transducer. Instruct the assistant to place the gel-coated US transducer in the sterile cover while you hold it. Have the assistant place sterile US gel over the transducer or on the patient. Place a sterile tourniquet near the shoulder. Reidentify the vein. Apply a 25 gauge needle onto a 10 mL syringe. Fill the syringe with local anesthetic solution. Inject local anesthetic solution subcutaneously and over the vein.

TECHNIQUE

The process of placing a PICC line uses the Seldinger technique (**Figure 62-6** and Chapter 63). **Observe several cardinal rules for the insertion of the PICC line. Always occlude the open hub of a needle or catheter to prevent an air embolism. Never let go of**

the guidewire to prevent its embolization into the central venous circulation. Never apply excessive force to the guidewire on insertion or removal. Doing so may injure the vessel, break the guidewire, and/or embolize the guidewire.

FIGURE 62-5. Chest radiograph confirming PICC line position. The catheter tip is located at the upper right atrium and slightly below the cavoatrial junction. (Courtesy of Mark R. Werley, MD.)

Attach the introducer needle to a 5 mL syringe containing 1 mL of sterile saline or local anesthetic solution. Use the specially designed introducer needle included with the PICC line as it has a relatively thin wall and a larger internal diameter relative to its external diameter. It has a shorter bevel than a conventional hypodermic needle. It has a tapered hub to guide the guidewire into the needle proper.

Insert the introducer needle at a 30° to 60° angle to the skin. Shallower angles are generally necessary in children whose vessels are smaller. Apply negative pressure to the syringe by withdrawing the plunger. Advance the introducer needle into the vein (**Figure 62-6A**). The vein's distance will vary depending on the patient's size and the target vessel's location. Veins have very low pressures within them and are easily collapsed by external pressure. If no blood is aspirated while withdrawing the needle, withdraw the introducer needle to the subcutaneous plane and redirect it. Avoid putting continuous pressure on the vein as gentle pressure may collapse the vein.

Stabilize and hold the introducer needle perfectly still with the nondominant hand once blood returns in the syringe. Remove the syringe. **Blood should flow slowly and freely from the hub of the needle.** The introducer needle is in an artery if blood squirts out the introducer needle hub. **Occlude the open hub of the introducer needle with the thumb of the nondominant hand while keeping the small finger of the hand in contact with the patient's skin.** The EP's proprioceptive reflexes will prevent movement of the

FIGURE 62-6. Insertion of the PICC line using the Seldinger technique. **A.** The vein is punctured by the introducer needle and blood is aspirated. **B.** The syringe has been removed. The guidewire is inserted through the introducer needle and into the vein. **C.** The introducer needle and guidewire sleeve are withdrawn over the guidewire. **D.** The skin puncture site is enlarged. **E.** The sheath-dilator unit is advanced over the guidewire until the hub is against the skin. **F.** The sheath-dilator unit and guidewire are within the vein. **G.** The guidewire and dilator have been removed and the sheath remains within the vein. **H.** The PICC line is inserted and advanced through the sheath. **I.** The peel-away sheath is removed, leaving the PICC line.

introducer needle by maintaining contact with the patient's skin. Even a millimeter of movement may result in failure to stay within the lumen of the vein.

Advance the guidewire through the introducer needle and into the vein (**Figures 62-6B and 62-6C**). The guidewire should advance easily into the vein. **Never force the guidewire.** Guidewire resistance may indicate that the introducer needle is not within the vein, is against the wall of a vessel, or is caught as the vessel bends. Slightly withdraw the guidewire, rotate it slightly, and readvance it. **The use of force will kink the guidewire and may cause it to damage the vein and adjoining tissues.** Advance the guidewire to the SVC or right atrium using fluoroscopy, length measurement estimates, or US.

Withdraw the introducer needle while securely holding the guidewire (**Figure 62-6C**). Grasp the guidewire as soon as the guidewire is visible between the tip of the introducer needle and the skin. Finish removing the needle over the guidewire.

Make a small incision in the skin adjacent to the guidewire using a #11 scalpel blade (**Figure 62-6D**). Place the peel-away sheath-dilator unit over the straight end of the guidewire (**Figure 62-6E**). Advance the peel-away sheath-dilator unit over the guidewire, through the skin, and into the vein (**Figure 62-6F**). A slight twisting motion as it is advanced may aid in its insertion. Continue to advance the peel-away sheath-dilator unit until its

hub is against the skin. **Do not release hold of the guidewire at any time.** Remove the dilator and guidewire as a unit and leave the peel-away sheath (**Figure 62-6G**).

Place the PICC line through the peel-away sheath (**Figure 62-6H**). Advance the PICC line and into the SVC or right atrium to the desired depth (**Figure 62-5**). Gently rolling or twisting the PICC line between the thumb and forefinger may aid in its advancement. Occlude the open PICC line lumen with the clamp attached to the PICC catheter to prevent an air embolism and excessive blood loss. Remove the peel-away sheath (**Figure 62-6I**).

Attach a syringe to the PICC line and aspirate blood to confirm that the catheter is within the vein. Withdraw any necessary blood samples from the catheter. Remove the syringe. Apply needleless caps to the ports of the PICC line (**Figure 62-3**). Securely attach the catheter to the skin with an adhesive dressing, nylon suture, a securing device, or silk sutures.^{6,10,11,23} Cover the skin puncture site with a sterile dressing.

A securing device is the Secure-A-Cath (Interrad Medical, Plymouth, MN). It securely holds the PICC line at the skin junction (**Figure 62-7**). It minimizes PICC line movement so the distal end does not migrate. It is faster than suturing with no potential needle stick. The device allows cleaning of the insertion site and repositioning of the PICC line. Several other securing devices are available from other companies.

PEDIATRIC CONSIDERATIONS

The procedure for PICC line placement can be done at the bedside by specially trained nurses, either with US guidance or other localization techniques. Placement by a physician in a procedure suite is indicated if this option is not available or unsuccessful.^{6,11,24} The complications in pediatrics are the same as those seen in an adult.²⁵

ASSESSMENT

Obtain a chest radiograph upon completion of the procedure to document and assess the position of the PICC line tip unless tip placement is visualized under fluoroscopy (Figure 62-5). Electrocardiogram (ECG) devices have been proven safe to use for catheter localization and have been implemented at the bedside during PICC line placement.²⁶⁻²⁸ Not all patients are candidates for ECG localization as it requires a rhythm with a normal-appearing P wave. It also requires additional training in ECG interpretation

for the provider placing the PICC line. Newer technologies incorporate multiple modalities (e.g., ECG and intravascular Doppler in conjunction with an algorithm) to accurately guide PICC line placement.²⁷

AFTERCARE

There is an immediate risk of thrombus formation, which can be a source of infection. Use saline flushing and heparin locking after each use, when not routinely being accessed, and at routine intermittent times. There is variation in the recommended dose of heparin and frequency of the flushes. Heparin solution can alter laboratory testing performed on blood drawn from the PICC line. Waste blood when drawing labs from an indwelling PICC line to account for any residual heparin.^{12,22} Draw blood from the lumen(s) of a PICC line with a syringe. Avoid using a vacuum tube collection device as it can collapse the catheter.^{15,22} Flushing regimens, dressing changes, permissible activities, and routine PICC line care are typically guided by institutional guidelines.^{21,22} **A PICC line can be used for weeks or months if it is cared for meticulously.**²²

Instruct the patient or caretaker to check the insertion site daily. It is easier to inspect if a transparent dressing is used. Instruct the patient to wash their hands and apply gloves before touching the insertion site or using the PICC line. Palpate the insertion site for focal tenderness. Educate the patient about the signs, symptoms, and significance of an infection. The patient should return to their primary physician or ED immediately if they develop any concerns, fever, chills, shortness of breath, redness, or pus at the puncture site. The patient should not use prefilled syringes of heparin or saline if they have leaks, the fluid appears cloudy or discolored, particles are seen in the fluid, or they are past the expiration date. Change the needleless connectors to the PICC line ports no less than every 72 hours or according to the instructions provided by the institution and manufacturer to reduce the risk of infection. Check the catheter for signs of breakage. **Use only compatible attachments.** The patient is often given extensive instruction sheets made by the institution that cover care and using the PICC line.

Scrub the needleless access caps with an appropriate antiseptic solution prior to being accessed.²⁹ **It is imperative to ensure the appropriate withdrawal of blood prior to any infusion.**¹⁵ **Clamp the catheter to prevent the rare possibility of an air embolism when needleless hubs are not in place or are being changed.**¹⁵

PICC LINE REMOVAL

A PICC line is typically removed by a representative of the insertion team. The process is simple if an EP needs to remove a PICC line.¹⁵ Remove any adhesive dressing or suture material holding the PICC line to the patient's skin. Clean the skin at the insertion site. Withdraw the PICC line from the patient. Apply pressure to the insertion site to tamponade any bleeding. Apply a bandage to the site.

COMPLICATIONS

There will always be complications associated with any procedure or invasive device. Some of the more common issues encountered with PICC lines are discussed below.

MALPOSITION

Difficulty in placing the PICC line or malposition can occur. PICC lines sometimes do not pass centrally and can get caught in the axilla or pass upward into the internal or external jugular veins.²⁰

It can be repositioned if caught early enough during the insertion. Delayed malposition of the catheter can occur if the PICC line is not secured correctly, especially at times of dressing changes. Frequent sliding of the catheter at the insertion site can be a source of phlebitis or infection. **Ensure the proper securing of the catheter to minimize this risk.**^{19,22} There is some movement of the PICC line with normal arm motion.¹² PICC line dislodgement may be due to iatrogenic issues, patient manipulation, or inappropriate patient movement.¹⁵

CATHETER DAMAGE

Damage to the PICC line from instruments, needles, or suture can occur during insertion and aftercare.³⁰ Damage external to the patient may be potentially repaired and salvaged. Consult the PICC line placement team for possible repair. There is the risk that the catheter can fracture and a fragment could migrate if damage occurs internally.³⁰ Apply a tourniquet to prevent proximal venous migration if it is witnessed. Removal of the broken piece may require a venous cut-down or retrieval by an Interventional Radiologist or Surgeon.²²

INFECTION

Any indwelling device is a possible source of infection. Infection rates for venous access devices peak within the first 3 months of placement, decrease some, and then plateau by 5 to 6 months after placement.¹⁵ PICC lines have a lower infection rate than some other venous access devices (e.g., nontunneled central venous catheters), but they do have a higher rate of infection than peripheral IV catheters.^{22,31,32} PICC line use in the inpatient setting has demonstrated higher catheter-associated infections than in the outpatient setting.^{22,32}

There are three major routes of PICC line contamination that can cause bacteremia. The infused solution can be contaminated, the skin at the insertion site can become contaminated, and direct contamination of the hub and lumen can occur. Intraluminal contamination is the most common etiology of catheter-related bacteremia.³³

Insertion-site infections rarely necessitate removal of the PICC line. These can often be treated with antibiotics in the absence of systemic symptoms or sepsis.²² It is often unclear initially if the source of a fever or sepsis is related to the indwelling PICC line. Obtain cultures from the insertion site if there are signs of a localized infection. Obtain blood cultures from the PICC line and a separate peripheral source. **The PICC line may remain in place with cultures pending if another source of fever is found.**²²

Decisions regarding catheter-related bloodstream infection rely on comparison of PICC line blood cultures to peripheral blood cultures or the time differential to positivity between PICC line and peripheral blood cultures. It can be presumed that the PICC line is the source of infection if the PICC line blood culture has colony counts higher than a predetermined threshold compared to the peripheral blood culture or the peripheral blood culture is negative. **Culture all PICC lines removed.**^{12,15}

The most common organisms associated with catheter-related bloodstream infection, in descending order of frequency, are coagulase-negative staphylococci, *Staphylococcus aureus*, enterococci, and *Candida* species.^{22,33} There are certain organisms in catheter-related bloodstream infections that require the catheter to be removed (i.e., *S aureus*, *Xanthomonas*, *Pseudomonas* species, mycobacteria, *Bacillus* species, *Corynebacterium* species, and *Candida* species). Other indications to remove the PICC line include endocarditis, osteomyelitis, sepsis with significant and persistent end-organ dysfunction, septic shock, and septic thrombophlebitis.^{15,22}

PICC lines are available as single-, double-, or triple-lumen catheters (**Figures 62-3 and 62-4**). PICC lines with more lumens and ports allow for the possible introduction of infection each time a port is accessed.¹² There is evidence to support an increased risk of infection with increased lumens. Use a PICC line with the minimum number of lumens needed for the goals of care to minimize the risk of infection.^{12,22,34} Antibiotic-coated PICC lines can decrease the rates of bacteremia and infection.³⁵

Some intraluminal infections can potentially be treated. This permits the PICC line to remain in place if it is the only remaining viable option for the patient, the risk of replacement is too great, or the risk of insertion of another venous access device is too great. Antibiotic-lock therapy is an option, alone or in conjunction with parenteral therapy. This permits high concentrations of antibiotics to be instilled into the catheter hub and remain in the catheter for a predetermined time. This so-called salvage helps eliminate bacteria that generate a biofilm (i.e., in and around the catheter) and prolong the use of the PICC line.^{15,22,32}

OCCCLUSION AND THROMBOSIS

Nonthrombotic causes of occlusion include kinking of the catheter, abutment of the catheter against the wall of the vessel, precipitations of infusions within the lumen, and catheter migration leading to tip malposition. A chest radiograph can indicate the proper location of the catheter tip, kinking, or radiographic evidence of damage.^{12,22} Abutment of the catheter against the vessel wall can often be resolved by a Valsalva maneuver or positional changes to the patient. Pinch-off of the catheter occurs when it is placed too medially and becomes compressed between the clavicle and the first rib. Patient positioning can be diagnostic and temporarily resolve the problem. The PICC line needs to be repositioned or replaced for long-term management.¹²

Thrombus is the most common cause of catheter occlusion (Figure 62-8).²² There are two main thrombotic causes of catheter

FIGURE 62-8. Digital subtraction venogram demonstrating complete occlusion of the subclavian vein (circled) with collateral formation. (Courtesy of Mark R. Werley, MD.)

occlusion. A fibrin sheath present on the tip or surrounding the catheter may act like a one-way valve. This permits flow of fluid through the catheter but not blood return. A complete occlusion is usually due to a collection of fibrin and platelets preventing the infusion of fluid and the return of blood. These two circumstances are considered appropriate indications for treatment with a small dose of a thrombolytic agent (Chapter 65).^{12,15} The agent of choice is guided by institutional guidelines.

Venous thrombosis is another complication that may arise.¹⁸ The risk of thrombosis has been documented to be as high as 50% and is one of the drawbacks to PICC lines.¹² Use of a PICC line with fewer lumens results in a smaller PICC line. Evidence supports decreased rates of thrombosis with fewer lumens.^{12,34} Venous thrombosis occurs more frequently if the tip is higher in the SVC and less frequently if it is in the lower SVC, right atrium, or cavoatrial junction.^{12,22} PICC lines have a higher rate of upper extremity deep vein thrombosis when compared to other forms of central venous access.^{14,18} Current recommendations for a catheter-associated deep vein thrombosis of the upper extremity include leaving the catheter in place and treating with anticoagulation therapy. Consider removal of the PICC line if it is malfunctioning, there are signs of infection, the patient has a contraindication to anticoagulation therapy, there are persistent or worsening signs of deep vein thrombosis despite appropriate therapy, or it is no longer required for treatment.³⁶

Another consideration is the long-term sequelae of prior PICC line placement. Stenosis or occlusion of the venous system may have developed along with the formation of collateral vessels in patients who have had previous PICC lines placed in the same anatomic location (**Figure 62-8**). This may lead to increased difficulty in placing subsequent PICC lines and require additional imaging to guide placement or insertion by an Interventional Radiologist. This is an important consideration in pediatric patients or other young patients with chronic illnesses who may require multiple repeated PICC lines over time.³⁷

ARRHYTHMIA

Cardiac conduction may be altered if the catheter contacts specific portions of the right atrium. **It is important to ensure the appropriate location of the PICC line and obtain an ECG upon completion of the procedure to avoid this complication.**¹²

SUMMARY

It is very unlikely that an EP may place a PICC line. It is feasible that a request may be placed to insert a PICC line for a patient in the ED. It is even more likely that an EP may deal with a patient presenting with a PICC line that needs to be accessed or presents with a complication. It is imperative that the EP be familiar with these catheters.

Central Venous Access

Arun Nagdev, Craig Sisson, Benjamin Thomas, and Peter Wroe

INTRODUCTION

Percutaneous cannulation of the central veins is an essential technique for both long-term and emergent medical care. Access to the major veins of the torso allows rapid high-volume fluid resuscitation, administration of concentrated ionic and nutritional solutions, and hemodynamic measurements.

Obtaining venous access is an essential skill for the Emergency Physician. Indications for peripheral venous access are broad, ranging from simple fluid and medication administration to delivery of intravenous (IV) contrast for imaging studies. Central venous access is less often compulsory but still remains an indispensable procedure in the practice of Emergency Medicine. Central venous access allows for multiple critical actions to be performed from the administration of blood products and vasoactive medications to transvenous cardiac pacing. Central venous access is often undertaken when peripheral IV access cannot be obtained.

Even the most experienced Emergency Physician can have difficulty securing rapid and functional access to the venous system in specific situations (e.g., cardiac arrest, injection drug users with sclerosed veins, obesity, and severe dehydration). The classical "blind" technique is based on anatomic and vascular landmarks. The growing integration of bedside ultrasound (US) into the practice of Emergency Medicine has slowly changed the way Emergency Physicians are choosing to perform central venous access. US visualization of the patient's vascular anatomy allows the specific advantage of determining the ideal location to access the central venous circulation. A thrombosed vein can be identified, which allows one to preemptively choose another site. The visualization of the overlap of the right internal jugular vein and the carotid artery may prevent inadvertent arterial puncture and the resultant sequelae in the anticoagulated patient. US guidance for central venous access has altered the clinical algorithm of obtaining vascular access, making the procedure easier to perform, and safer for the patient.

Evidence supporting US guidance for central venous access is fairly robust.¹⁻⁵ Convincing data from the Critical Care and

Emergency Medicine literature indicates an increased success rate and a decrease in the complication rates. The Agency for Healthcare Research and Quality and National Institute for Clinical Excellence recommended US guidance for central venous access. The availability of small, low-cost, and portable US machines has made US guidance for central venous access a requisite skill for all Emergency Physicians. A brief description of US-guided central venous access is discussed in the following sections as appropriate. Refer to Chapter 64 for the complete details.

ANATOMY AND PATHOPHYSIOLOGY

The tip of the central venous catheter must lie in the superior or inferior vena cava and never in the right atrium. The thin wall of the right atrium may easily be perforated by the catheter tip and result in complications (e.g., hemorrhage and cardiac tamponade). The central venous anatomy is shown in **Figure 63-1**. The superior vena cava is accessed through the internal jugular veins, the subclavian veins, and less commonly the external jugular veins. The inferior vena cava is accessed through the femoral veins. These access routes are discussed in greater detail in the corresponding sections below. The advantages and disadvantages of each route for central venous access are summarized in **Table 63-1**.

INTERNAL JUGULAR VEIN

The internal jugular vein is not directly visible from the surface of the skin. A thorough knowledge of its anatomic relationships is essential for successful cannulation. The internal jugular vein is a direct continuation of the sigmoid sinus and exits the skull through the jugular foramen, just anteromedial to the mastoid process.⁶ It joins the subclavian vein deep and just lateral to the head of the clavicle (**Figure 63-2**).⁶ The internal jugular vein drains blood back to

FIGURE 63-1. The anatomy of the central venous system.

TABLE 63-1 Characteristics of the Different Routes for Central Venous Cannulation

	Internal jugular vein	External jugular vein	Subclavian vein	Femoral vein
Risk of infection	Low	Low	Low	High
Patient mobility	Fair	Poor	Good	Bedridden
Trendelenburg required	Yes	Yes	Yes	No, best for congestive heart failure or dyspnea
Need to stop CPR	Probably	Probably	Yes	No, may continue CPR
Suitable for long-term use	Yes, but not if ambulatory	No	Yes—best choice	No, remove within 2–3 days
Risk of venous thrombosis	Low	Low	Low	High

the heart from the brain, face, and neck. There is a proximal and distal dilatation of the vein known as the superior and inferior bulbs of the internal jugular vein. The inferior bulb contains a bicuspid valve to prevent retrograde flow. The surface projection of the internal jugular vein runs from the earlobe to the medial clavicle, between the sternal and clavicular heads of the sternocleidomastoid muscle. The internal jugular vein increases in diameter as it descends. It is joined by tributary veins in the upper neck, which make it easier to cannulate below the level of the cricoid cartilage. The left internal jugular vein is smaller than the right internal jugular vein.⁷⁻⁹ This is one reason the right internal jugular vein is the choice for vascular access.

The internal jugular vein is collapsible (Figure 63-3). Its overall diameter is dependent on the intravascular volume status and patient position. It has a very small diameter in low-flow states (e.g., during cardiopulmonary resuscitation [CPR] and when the patient is upright). The vein is easily compressible and will collapse with gentle external pressure from a palpating finger or a large-diameter needle indenting the skin (**Figure 63-3B**). Local masses (e.g., a goiter, hematoma, or tumor) can easily collapse the internal jugular vein. The internal jugular vein is very distensible. Placing the patient in the Trendelenburg position or having the patient perform

the Valsalva maneuver will distend the vein and make it easier to locate and cannulate (**Figure 63-3C**).

The internal jugular vein lies in proximity to the carotid artery, vagus nerve, phrenic nerve, brachial plexus, cervical sympathetic plexus, thyroid gland, and the pleural cupula of the lung along its course. The inferior portion of the left internal jugular vein lies in proximity to the thoracic duct. **The location of these structures places them at risk for injury during central venous cannulation of the internal jugular vein.**

The position of the internal jugular vein in relation to the common carotid artery within the carotid sheath can vary considerably between individuals. The simple assumption that the internal jugular vein is always lateral to the carotid artery has not borne out in ultrasonographic studies. Overlap with the carotid artery can vary from 0% to 100% depending on individual anatomic variation, patient positioning, and where along its course the internal jugular vein is imaged.¹⁰⁻¹⁵ It can lie medial to the carotid artery in some patients, making blind needle puncture nearly impossible and extremely dangerous.^{10,11,15}

This variability in location is mirrored by the size variability of the internal jugular vein.^{8,16,17} The size of the internal jugular vein can vary widely for anatomic and physiologic reasons. A vein diameter of less than 0.7 cm may be an independent risk factor for unsuccessful venous cannulation.¹⁸ The internal jugular vein can vary in size and location when comparing the right side to the left side and the proximal vein to the distal vein.^{8,10,13,16} Each of these individual factors forms a strong argument for ultrasonographic assistance during internal jugular vein central line placement.

The common carotid artery travels alongside the internal jugular vein and is an important anatomic landmark for locating the internal jugular vein. The carotid artery runs deep and slightly anterior to the internal jugular vein. The left internal jugular vein usually overlaps the carotid artery in the lower neck (**Figure 63-3A**). The right internal jugular vein and the right carotid artery are usually separated slightly.

The right internal jugular vein is generally preferred to the left internal jugular vein as the site of central venous cannulation. The right internal jugular vein provides a nearly direct route to the superior vena cava. The dome of the right lung is somewhat lower than that of the left lung and decreases the chance of an iatrogenic

**FIGURE 63-2.** Anatomy and surface relationships of the internal jugular vein.

C

FIGURE 63-3. Transverse US images of the left internal jugular vein (IJV) and carotid artery (CA). **A.** The patient is supine. **B.** The low-pressure internal jugular vein collapses easily while the carotid is still patent with gentle external pressure. **C.** The Valsalva maneuver or placement of the patient in the Trendelenburg position dilates the internal jugular vein.

pneumothorax. The thoracic duct is relatively large and lies high in the left chest. These favor the right internal jugular approach to central venous cannulation to minimize complications.

There are three main “blind” or landmark approaches to the internal jugular vein as defined by their relationship to the

FIGURE 63-4. Central approach to the right internal jugular vein.

sternocleidomastoid muscle. These are the anterior, central, and posterior approaches (**Figures 63-4, 63-5, and 63-6**). The central approach is most commonly used. These three approaches are summarized in **Table 63-2** and described later in this chapter.

SUBCLAVIAN VEIN

The subclavian vein begins as the continuation of the axillary vein at the lateral edge of the first rib (**Figure 63-7**). The subclavian vein courses anterior to the anterior scalene muscle, which separates it from the subclavian artery. The subclavian vein descends to join the internal jugular vein and form the brachiocephalic trunk, which empties into the superior vena cava. **US visualization of the vein**

FIGURE 63-5. Anterior approach to the right internal jugular vein.

FIGURE 63-6. Posterior approach to the right internal jugular vein.

is not usually possible because the subclavian vein lies directly underneath the clavicle.

The subclavian veins are 1 to 2 cm in diameter in an adult. Fibrous connective tissue joins the subclavian vein to the clavicle and first rib, preventing collapse of the vessel even in the event of a low-flow state. Anatomically associated structures include the thoracic duct which joins the left subclavian vein at its junction with the left internal jugular vein. The right subclavian vein is preferred to the left for central venous access for this reason. The domes of the pleura lie posterior and inferior to the subclavian veins and medial to the anterior scalene muscles. The subclavian arteries lie immediately posterior to the veins (Figure 63-7).

Subcutaneous fatty tissue, chest morphology, the close proximity of the pleura, and the close proximity of the subclavian artery make the subclavian vein the least favored site for central venous access in children. This is especially true in infants. An experienced Emergency Physician must perform the procedure if this route must be used in a neonate, infant, or small child.

AXILLARY VEIN

The axillary vein is defined as the continuation of the brachial vein from the medial border of the teres major to the lateral border of the first rib. The axillary vein continues under the clavicle as the

subclavian vein, which then joins the internal jugular vein to form the brachiocephalic vein (Figure 63-2). Cadaver-based and radiologic studies have demonstrated a great variation in the anatomic relationship between the axillary vein and artery.^{19,20} This makes the blind or landmark technique difficult for even the most experienced Emergency Physician.^{19,20} A US study of the axillary vein in volunteers demonstrated a decrease overlap between the axillary vein and artery and a farther distance from the pleura as it was followed laterally.²¹

FEMORAL VEIN

The femoral vein is a continuation of the iliac vein after it crosses the inguinal ligament (Figure 63-8). The femoral vein lies within the femoral sheath and just medial to the femoral artery in the groin. This relationship can be remembered by the mnemonic “toward the NAVEL.” This describes the contents of the femoral sheath from medial to lateral (i.e., femoral Nerve, femoral Artery, femoral Vein, Empty space, and Lymphatics). The femoral artery lies at the midpoint of the line connecting the symphysis pubis and the anterior superior iliac spine.^{22,23} The femoral vein lies approximately 1 cm medial to the femoral artery pulse in an adult and approximately 0.5 cm medial in infants and young children.^{24,25}

Recent anatomic US surveys on adult and pediatric populations have demonstrated variation in the classical anatomic teaching. There is an increased overlap between the femoral vein and artery as they move distally to the inguinal ligament.²⁶ A study evaluated the amount of venous and arterial overlap in euvoletic children 1 cm distal to the inguinal ligament.²⁷ The femoral vein had either partial or complete overlap with the femoral artery in 12% of the patients. **These studies and others have noted the great variability of the vascular venous anatomy and recommend US visualization before femoral venous cannulation attempts.**²⁶⁻³⁰

The puncture site for femoral vein cannulation lies medial to the femoral artery and inferior to the inguinal ligament (Figure 63-8).^{22,23,31} **Perform femoral venous cannulation 1 to 2 cm inferior to the inguinal ligament to prevent inadvertent intraabdominal external iliac vein puncture.** The femoral vein becomes the external iliac vein superior to the inguinal ligament (Figure 63-8). **Blood can flow freely into the retroperitoneal space, forming a potentially large and externally invisible hematoma if the posterior wall of the femoral vein is punctured by a through-and-through needle track above the inguinal ligament. It is imperative to puncture the femoral vein inferior to the inguinal ligament.**

The femoral vein remains a popular route for access to the central circulation due to its relative ease of placement.³² A large, randomized, multicenter study questioned the classically held notion that the femoral venous cannulations have higher rates of infection.³³ The study did not demonstrate a higher rate of infection between catheter tips removed from the femoral vein and the internal jugular vein. The rate of catheter-related bloodstream infection between femoral vein cannulation and internal jugular vein cannulation was similar.

TABLE 63-2 Approaches to the Internal Jugular Vein

	Central	Anterior	Posterior
Insertion landmark	Superior apex of the triangle formed by the two heads of the sternocleidomastoid muscle and the clavicle	Medial edge of the sternocleidomastoid muscle at level of thyroid cartilage	Lateral edge of sternocleidomastoid muscle, 1/3 of the way from the clavicle to the mastoid process
Angle with skin	30° (child), 45–60° (adult)	30° (child), 45° (adult)	30–45°, dive under the border of the sternocleidomastoid muscle
Aim toward	Ipsilateral nipple	Ipsilateral nipple	Sternal notch
Internal jugular vein depth in an adult	Within 3 cm	Within 3 cm	Within 5 cm

The anatomy of the subclavian vein. **A.** The right subclavian vein. **B.** Magnified view of the right subclavian vein demonstrating adjacent structures that may be injured during attempted cannulation. **C.** Sagittal section through the mid-clavicle. Note that the first rib protects the subclavian artery during an infraclavicular approach to the subclavian vein. **D.** Sagittal section through the medial third of the clavicle. Note the proximity of the subclavian artery and pleural dome.

CENTRAL VENOUS ACCESS IN THE OBESE PATIENT

Central venous access is more complicated in the obese patient.³⁴ Surface landmarks may be obscured by adipose tissue and skin folds. The clavicle, carotid artery pulses, thyroid cartilage, and

trachea can be difficult to palpate. This makes internal jugular and subclavian venous access problematic. The anterior superior iliac spine, femoral artery pulse, and pubic symphysis can be difficult to palpate. This makes femoral venous access problematic. Femoral venous access is often performed lower than normal due to an overhanging pannus. Placing the obese patient in the Trendelenburg position may not be possible. They may decompensate in this position due to their poor pulmonary reserves, decreased lung and tidal volumes, increased intraabdominal pressure against the diaphragm, and difficult airway anatomy. All these factors may increase the rate of complications in the obese patient.

INDICATIONS

The internal jugular route is acceptable for central venous access in most cases. Take into consideration the patient's age, build, expected duration of line placement, health status, medical history, and risk of infection when determining the site of placement. It allows ready access to the superior vena cava for long-term central venous access, caustic infusions, and monitoring of central venous pressure. Pulmonary artery catheters and transvenous pacing wires can be introduced through the right internal jugular vein. The internal jugular vein is accessible without terminating CPR efforts, although chest compressions and the lack of carotid pulsations make accessing it

FIGURE 63-8. Anatomy of the femoral vein.

difficult. The risk of an iatrogenic pneumothorax is probably less with internal jugular vein cannulation as opposed to the subclavian vein, although patient mobility is less and discomfort is greater. The internal jugular vein puncture site is compressible in the coagulopathic patient, but a hematoma formation may lead to airway compromise. Patients historically labeled as having “difficult access” had very low complication rates using US-guided central venous access of the internal jugular vein.³⁵ Approximately 28% of the total procedures performed were on patients with disorders of hemostasis. Access to the internal jugular vein and subclavian vein is safe in patients with a coagulopathy.^{36,37}

The subclavian vein is the preferred route for long-term central venous access. This site allows for ambulation (unlike a femoral line) and neck movement without discomfort (unlike an internal jugular line). The catheter is concealable under clothing and makes outpatient use more acceptable.

The axillary vein is not a commonly used venous access site. It is more commonly used in children for long-term access. The use of US guidance has allowed the axillary vein to be an alternate access site. **The axillary vein should only be cannulated in thin patients and as an alternative site when other sites are not available, have failed, or are contraindicated due to the depth of the vessel and its proximity to the brachial plexus.**

The femoral vein is often the preferred route for emergent central venous cannulation. The indications are the same as for any other site with a few exceptions. The femoral vein is not a suitable route for ambulatory patients beyond the initial resuscitation and stabilization period. Patients with femoral central venous lines must be confined to bed. Femoral venous access is easily obtained in patients with respiratory distress and pulmonary edema since they do not need to be placed in the Trendelenburg position. Femoral venous access is relatively easy during CPR and does not require the cessation of chest compressions. The femoral vein is easily compressible. This makes it preferable to the subclavian vein in coagulopathic patients or those undergoing thrombolysis, although peripheral access would be preferred in these cases.⁶ There is no risk of injury to the airway, pleura, or carotid arteries in very young or combative patients. Femoral central venous lines are generally preferred for initial central venous access in the very young or combative patient if deep sedation or neuromuscular paralysis is contraindicated or otherwise unnecessary.

CONTRAINDICATIONS

The usual contraindications to any invasive procedure apply to central venous access. Cellulitis or overlying infection at the puncture site is a contraindication to central venous access. A mass or hematoma causing external compression and/or obliteration of the vessel lumen, an intraluminal thrombosis, or a small size vein when visualized by US are contraindications. Seek an alternative if the patient is combative, agitated, or uncooperative. These patients require sedation and/or paralysis prior to insertion of the central venous line. Distorted anatomic landmarks (i.e., deformities, fractures, obesity, previous catheterization at the site, surgery, or trauma) are relative contraindications. There is a small but real risk of serious morbidity and even death due to the procedure. **Do not place a central venous line unless a peripheral IV line is inadequate or unobtainable and unless personnel capable of managing the procedural complications are immediately available.**

INTERNAL JUGULAR VEIN CANNULATION

Anatomic distortion of the neck (e.g., subcutaneous emphysema or a hematoma) may make placement of an internal jugular line difficult and hazardous. Known severe carotid artery stenosis or

atherosclerosis on the desired side of cannulation is a relative contraindication to internal jugular vein cannulation. Accidental carotid artery puncture during line placement may result in plaque rupture and a subsequent stroke. The vein may be collapsed and difficult to access in the hypovolemic patient. Other contraindications to cannulating the internal jugular vein include actual or suspected cervical spine fractures and penetrating neck injuries. Do not cannulate the ipsilateral internal jugular vein if the patient has an implanted pacemaker or defibrillator.³⁸ Central venous access can result in needle injury to the leads, lead displacement, and thromboembolism.

The subclavian or femoral route may be preferable in some circumstances. The subclavian route is a better choice for long-term lines in ambulatory patients and for hemodialysis. The limited neck mobility due to an internal jugular line is very uncomfortable. Ongoing or impending thrombolytic administration is a relative contraindication to internal jugular puncture. A femoral central venous line is preferable. Successful internal jugular cannulation requires the patient to be placed supine and preferably in 15° to 30° of Trendelenburg tilt. This may be impossible in a patient with severe pulmonary compromise, and the femoral route is preferred. Internal jugular vein cannulation is difficult in children under 1 year of age due to poor landmarks and a very short neck. Internal jugular cannulation is contraindicated in any child who cannot be adequately immobilized or is paralyzed after insertion of the central venous line. Internal jugular cannulation will be more difficult if the patient's neck cannot be turned. The more rotation applied to the neck, the greater is the vascular overlap between the internal jugular vein and carotid artery. This will increase the risk of arterial puncture. Head rotation should be minimized if a blind technique is used. US guidance can minimize head rotation and free the Emergency Physician from the historical anatomic approaches. This allows for any needle approach to be used depending on the location of the internal jugular vein in relation to the carotid artery.

A left bundle branch block is a relative contraindication to central venous cannulation. The guidewire can induce complete heart block when it enters the right ventricle.³⁹ Extreme caution should be used if an internal jugular or subclavian central line is necessary. **Avoid inserting the guidewire into the heart.** Continuous cardiac monitoring should be used, and transcutaneous and transvenous cardiac pacing equipment should be readily available.

SUBCLAVIAN VEIN CANNULATION

The subclavian vein is incompressible and should be accessed with care in any patient who is coagulopathic. Current or imminent systemic thrombolysis is an absolute contraindication to placing a subclavian vein catheter.⁶ Perform subclavian vein cannulation on the contralateral side if the patient is relying on a single lung. Chest wall deformities, distorted anatomy, and suspected vascular injury to the chest or ipsilateral upper extremity are contraindications. This route should be avoided if the patient has had prior surgery or trauma to the clavicle, the first two ribs, or the subclavian vessels. Do not cannulate the ipsilateral subclavian vein if the patient has an implanted pacemaker or defibrillator.³⁸ Central venous access can result in needle injury to the leads, lead displacement, and thromboembolism.

AXILLARY VEIN CANNULATION

US-guided axillary vein cannulation can be difficult for the Emergency Physician inexperienced in accessing this vein. **Use the axillary vein as an access point only when other central veins are not accessible or contraindicated and the Emergency Physician is comfortable with the procedure of US-guided vascular access.** The depth of the axillary vein, commonly > 3 cm, makes access difficult in patients who are not thin. The proximity of the brachial

plexus can result in significant injury if the needle penetrates it. The length of the catheter may be too short to reach the superior vena cava if placed in the left axillary vein.

FEMORAL VEIN CANNULATION

Contraindications to femoral line placement include infection, venous thrombosis, or significant trauma to the ipsilateral lower extremity or groin area. Abdominal trauma may result in an interruption of the inferior vena cava, allowing any infused fluid or blood to flow into the abdomen rather than into the central circulation. Blood return below the diaphragm is reduced during CPR, and a femoral catheter must end near the level of the diaphragm for medications to be most effective.

Catheterization via the internal jugular vein or subclavian vein is usually easier if the purpose of central venous access is pulmonary artery catheterization or transvenous cardiac pacing. These procedures often require fluoroscopy when they are performed through the femoral vein. Central venous pressures measured through a femoral vein catheter may be inaccurate unless the patient is perfectly supine.

EQUIPMENT

- Sterile gloves and gown
- Facemask and cap
- Povidone iodine or chlorhexidine solution
- Sterile drapes or towels
- Local anesthetic solution
- 25 gauge needle
- 5 mL syringes
- “Finder” needle, usually 22 gauge for an adult
- 5 mL syringe with a nonlocking hub
- Thin-walled introducer needle or catheter-over-the-needle
- Guidewire
- Gauze 4×4 squares
- Central venous line
- Dilator
- #11 scalpel blade
- Nylon or silk suture, 3–0 or 4–0
- Sterile saline
- Needle driver
- Tape and catheter site dressing material
- Catheter clamp, if supplied with the kit

A variety of standard kits are commercially available (**Figure 63-9**). They contain all required equipment. The appropriate catheter should be chosen based on the patient's needs. The optimal catheter lengths for patients of different ages are summarized in **Table 63-3**.

Catheters with between one and four lumens are available. Multiple-lumen catheters are available in a variety of sizes and allow simultaneous venous pressure measurement, administration of medications, and venous sampling without disconnecting the infusion apparatus. Disadvantages of multiple-lumen catheters over single-lumen catheters include smaller lumen sizes for a given catheter's outside diameter, greater cost, and the need to maintain unused lumens to prevent them becoming thrombosed. There is probably no increased risk of infection in using triple-lumen versus single-lumen catheters.^{40–42} Some comparisons between these devices are summarized in **Table 63-4**.

A

B

FIGURE 63-9. Equipment needed for central venous catheterization. **A.** A commercially available central venous line kit. **B.** Examples of different catheter types available. From left to right: single-lumen, double-lumen, triple-lumen, and introducer sheath (Cordis).

Percutaneous sheaths are intended primarily for the introduction of intravascular devices (e.g., pulmonary artery catheters and transvenous pacing wires). They are most often used in the Emergency Department as a large-bore line for the rapid resuscitation of hypotensive and hypovolemic patients. Sheaths are available in many sizes and configurations. Many models have an adjustable hemostasis valve that may be removed and a side port that allows infusion while the main lumen is being used for monitoring.

The equipment required for subclavian vein cannulation is the same as that for internal jugular vein cannulation. Subclavian vein catheters must be slightly longer or inserted farther than internal jugular vein catheters. Left-sided catheters must be a few centimeters longer or inserted farther than right-sided catheters. The longer

TABLE 63-3 Catheter Sizes, Types, and Characteristics

Catheter size (French)	Number of lumens	Patient size	Venous access site	Minimum catheter length (cm)*
2	1	Infant	Femoral, internal jugular, external jugular, or subclavian	5
3	1	< 5 kg	Femoral, internal jugular, external jugular, or subclavian	5
4	1,2	5–10 kg	Femoral	5
		10–15 kg	Femoral, internal jugular, external jugular, or subclavian	8–12
5	1, 2, 3	> 15 kg	Femoral, internal jugular, external jugular, or subclavian	12–25
7	1 (sheath), 2, 3	>40 kg	Femoral, internal jugular, external jugular, or subclavian	15–25
8 and larger	1 (sheath), 2, 3, 4	Adult	Femoral, internal jugular, or subclavian	15–25

*The longer end of the catheter length range is for use in the subclavian veins, with the longest catheters needed for the left subclavian vein.

needle should be used for subclavian vein cannulation if the kit used has two different lengths of introducer needles.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain an informed consent for the procedure unless it is being performed emergently. Place the patient in the Trendelenburg position if catheterization of the internal jugular vein is being attempted. Position the patient in at least 15° of Trendelenburg to prevent an air embolism. Slightly rotate the patient's head toward the side opposite that to be cannulated. A large degree of head rotation has been shown to increase the overlap between the internal jugular vein and carotid artery, theoretically increasing the risk of carotid artery puncture.⁴³

The subclavian vein is fixed to the surrounding tissues and will neither collapse nor distend. **The Valsalva maneuver or the extreme Trendelenburg position is not necessary.** Head rotation is neither necessary nor helpful. Slightly abduct the patient's arm on the side to be cannulated. Avoid placing rolled towels between

the shoulder blades as this can decrease the distance between the clavicle and first rib, compress the subclavian vein, and make the procedure more difficult.⁴⁴ Placement of rolled towels between the shoulder blades decreases the overlap between the carotid artery and internal jugular vein.⁴⁵

Place the patient supine or in slight reverse Trendelenburg if femoral vein catheterization is being attempted. The reverse Trendelenburg position will increase the cross-sectional area of the femoral vein.⁴⁶ The Trendelenburg position is contraindicated due to the risk of venous air embolism. Slight external rotation and abduction of the extremity may increase the amount of femoral vein accessible for cannulation.⁴⁷ It is easier for a right-handed Emergency Physician to perform the procedure on the patient's right side, regardless of which femoral vein is being accessed. The opposite is true for those who are left-handed. Do not abduct or externally rotate the patient's hip as this may increase the overlap of the femoral vessels.⁴⁸

Identify the anatomic landmarks for the procedure after positioning the patient. Clean any dirt and debris from the area of the puncture site. Apply povidone iodine or chlorhexidine solution and allow it to dry.⁴⁹ Chlorhexidine solutions may be more effective at preventing infections.⁵⁰ **It is recommended to prepare the entire neck and clavicular area if the internal jugular or subclavian routes are attempted so that, if access to one site is unsuccessful, another site may be accessed without repeat prepping and draping. Due to the risk of inducing a pneumothorax, attempts at contralateral internal jugular or subclavian vein cannulation after an unsuccessful attempt must be delayed until a chest radiograph is checked to prevent bilateral pneumothoraces.**

Infiltrate the subcutaneous tissues at the needle puncture site with a generous volume of local anesthetic solution, including any areas that will be used for suturing the catheter in place. This allows the local anesthetic to diffuse throughout the area and take effect before the main procedure begins. Any distortion of anatomic landmarks caused by anesthetic infiltration decreases as the anesthetic is absorbed into the subcutaneous tissues.

Apply electrocardiographic monitoring, pulse oximetry, and noninvasive blood pressure monitoring to the patient and administer supplemental oxygen. Electrocardiographic monitoring during insertion of a central line is recommended due to the risk of ventricular dysrhythmias if the guidewire or catheter enter the right ventricle. It is preferable to have a designated person whose only job is to watch the monitoring equipment. The patient's face and chest will be draped for the internal jugular or subclavian vein cannulation procedure. The Emergency Physician will be focused on the procedure and is often unaware of any sudden patient deterioration, ventilator disconnect, or other irregularities. Resuscitation equipment should be immediately available. A postinsertion chest radiograph to verify line placement and the lack of a pneumothorax must be immediately available. Bedside ultrasound can be used to ensure lack of a pneumothorax as well as proper placement of the catheter tip.

Prepare for the procedure. Apply sterile gloves, a sterile gown, a hat, and a face mask. Some Emergency Physicians prefer to double-glove. If one glove becomes contaminated, it can be discarded and the procedure continued without interruption. Open the desired venous access kit using aseptic technique on a bedside table. Perform a quick inventory and identify all necessary equipment before beginning the procedure. Set up a sterile field next to the patient and within easy reach. Place the equipment that must be immediately at hand on the sterile field. This includes a sterile drape, syringe, large-bore hollow needle, guidewire, and gauze squares. Any other equipment, including the catheter itself, may be temporarily left in the kit. **Never use the patient as a table.** Everything can fall onto the floor if the patient moves. A needle-stick injury can occur from the falling needles or if the instinct to grab the falling equipment occurs.

TABLE 63-4 Comparisons between Central Venous Catheter Types

	Single lumen	Multiple lumen	Sheath (Cordis)
Minimum outer diameter	Smallest	Intermediate	Largest
Infusion rate	Moderate	Lowest (resuscitation catheters with larger lumen available)	Fastest (for central lumen; side port is slower)
Simultaneous infusions, or infusion while monitoring	No	Yes	Yes, if central lumen and side port both used
Length	Varies, fairly long	Long	Short
Allows device insertion (pulmonary artery lines and transvenous pacemakers)	No	No	Yes

A difficulty arises in how far the central venous line is inserted. A guideline using equations was determined to predict the length of catheter to insert, reduce complications, and save time.⁵¹ The equations for insertion length are simple to remember for the right subclavian vein [i.e., $(\text{height} \div 10) - 2 \text{ cm}$], left subclavian vein [i.e., $(\text{height} \div 10) + 2 \text{ cm}$], right internal jugular vein (i.e., $\text{height [cm]} \div 10$), and left internal jugular vein [i.e., $(\text{height} \div 10) + 4 \text{ cm}$].

INTERNAL JUGULAR VEIN CATHETERIZATION TECHNIQUES

CENTRAL APPROACH TO THE INTERNAL JUGULAR VEIN

While an internal jugular vein cannula can be inserted using the over-the-needle and through-the-needle techniques, the Seldinger technique is often preferred.^{52,53} See Chapter 59 and Table 63-5 for a more complete discussion. The Seldinger technique uses a flexible guidewire inserted through a thin-walled hollow needle to guide a catheter of any desired length through the skin and into the central circulation. This technique is described below and summarized in Table 63-6.

Clean, prep, and drape the area as described previously. Place the patient in the Trendelenburg position with their head down 15° to 30°. Slightly rotate the patient's head away from the side that will be cannulated. Excessive rotation will distort the anatomic landmarks and may bring the internal jugular vein closer to the carotid artery.^{43,54,55}

Observe several cardinal rules for the insertion of the catheter. Always occlude the open hub of a needle or catheter in a central vein to prevent an air embolism. Never let go of the guidewire to prevent its embolization into the central venous circulation. Never apply excessive force to the guidewire on insertion or removal. Doing so may injure the vessel, break the guidewire, and/or embolize the guidewire.

Attach the introducer needle to a 5 mL syringe containing 1 mL of sterile saline or local anesthetic solution. The specially designed introducer needle included with the catheter should be used, as it has a relatively thin wall and a larger internal diameter relative to its external diameter. It has a shorter bevel than a conventional hypodermic needle. It has a tapered hub to guide the guidewire into the needle proper.

If there is doubt about the exact location of the vein, it may first be located with a small “finder” needle. Insert a 25 or 27 gauge needle attached to a 5 mL syringe through the skin puncture site previously chosen. Advance the needle at a 30° to 60° angle to the skin while applying negative pressure to the syringe. A flash of blood signifies that the tip of the needle is within the vein. Note the depth and location of the vein. Remove the finder needle. Alternatively, the finder needle may be left in place for reference.

Insert the introducer needle at a 30° to 60° angle at the apex of the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle and the clavicle (Figure 63-4). This point is just lateral to the carotid artery pulse. Direct the introducer needle toward the ipsilateral nipple. Shallower angles make it necessary to traverse a greater amount of subcutaneous tissues and structures before entering the vessel. Steeper angles make insertion of the catheter over the guidewire difficult, as the guidewire tends to kink. Shallower angles are generally necessary in children whose vessels are smaller. Inject a small amount of the fluid in the syringe to remove any skin plug that may block blood return once the vein has been penetrated.

Apply negative pressure to the syringe by withdrawing the plunger. Advance the introducer needle into the vein (Figure 63-10A). The vein's distance will vary depending on the patient's size and the target vessel's location. Stop advancing the introducer needle if the vein is not located within 3 to 5 cm of the skin. Withdraw the needle slowly while continuing to aspirate. The vessel will often have been completely traversed, and no blood will return due to collapse of the vein by the pressure of the skin being forced inward as the introducer needle passes through it. Veins have very low pressures within them and are easily collapsed by external pressure. If no blood is aspirated while withdrawing the needle, withdraw the introducer needle to the subcutaneous plane and redirect it slightly medially. Avoid putting continuous pressure on the carotid artery pulse, as even gentle pressure may collapse the internal jugular vein (Figure 63-3B).

Stabilize and hold the introducer needle perfectly still with the nondominant hand once blood returns in the syringe. The carotid artery has been entered if the blood is bright red and/or forces the plunger of the syringe back. Remove the syringe. **Blood should flow slowly and freely from the hub of the needle.** The introducer needle is in the carotid or subclavian artery if blood squirts out the introducer needle hub. If blood dribbles out or does not flow from the hub and the patient has spontaneous circulation, reattach the syringe and reposition the introducer needle until free flow is obtained. Occlude the open hub of the introducer needle with the thumb of the nondominant hand while keeping the small finger of the hand in contact with the patient's skin. The Emergency Physician's proprioceptive reflexes will prevent movement of the introducer needle by maintaining contact with the patient's skin. Even a millimeter of movement may result in failure to stay within the lumen of the vein.

Prepare the guidewire (Figure 63-11). Grasp the guidewire and its sleeve with the dominant hand. The tip of the guidewire has a “J” shape when the sleeve is retracted (Figure 63-11A). Slide the sleeve forward to straighten out the “J” of the guidewire (Figure 63-11B). Insert the guidewire sleeve into the hub of the introducer needle (Figures 63-10B and 63-11C). Advance the guidewire through the sleeve and into the introducer needle. **Never let go of the guidewire. One end of the guidewire must always be held to prevent its loss and embolization into the central circulation.**

Do not simply reverse the guidewire if the sleeve used to straighten the curved end of the guidewire is lost. The straight end of the guidewire can puncture the wall of the vein. Grasp the guidewire between the fourth and fifth fingers and the palm of the dominant hand (Figure 63-12A). Apply gentle traction on the curved guidewire tip with the thumb and the second fingers to straighten the guidewire (Figure 63-12B). The guidewire can then be inserted into the introducer needle hub without the use of the sleeve.

Advance the guidewire through the introducer needle and into the vein (Figure 63-10B). The guidewire should advance easily into the vein. **Never force the guidewire.** Guidewire resistance may indicate that the introducer needle is not within the vein, is against the wall of a vessel, or is caught as the vessel bends. Slightly withdraw

TABLE 63-5 Comparison of Central Venous Catheterization Methods

	Seldinger	Catheter-over-the-needle	Catheter-through-the-needle
Insertion needle	Small	Large	Largest
Speed	Slowest	Fastest	Fast
Number of steps	4+	1	2
Risk of catheter shear	None	Low	Highest
Catheters and lumens available	Single- or multiple-lumen, sheath/introducer	Single-lumen only	Single-lumen only
Rate of infusion	Highest (with sheath)	Moderate	Low to moderate

TABLE 63-6 Summary of the Seldinger Method of Central Venous Cannulation*

Step	Action	Tips and caveats
1	Prep and drape the skin puncture site.	For internal jugular vein, prepping down to the clavicle and up to the jaw will enable an attempt at the ipsilateral subclavian vein (or vice versa).
2	Anesthetize the puncture site if not already done.	Anesthetize the suture sites also.
3	Uncap the distal lumen.	Additional lumens may be flushed at this point or after insertion, as desired.
4	Locate the vein using the finder needle and aspirating syringe.	Internal jugular vein should be reached within 3 cm. Stop advancing after 4–5 cm if the vein is not located.
5	Remove the finder needle, noting the direction and depth of the internal jugular vein. Or withdraw the needle slightly so it is outside the internal jugular vein and leave it in place as a guide.	A few drops or a line of blood may be left on the skin as the finder is withdrawn to show the proper direction.
6	Insert introducer needle on a syringe along the “finder’s” path until venous blood is aspirated. Alternatively, an introducer catheter and needle assembly can be used to cannulate the internal jugular vein; the needle is then withdrawn.	Syringe must have a nonlocking hub. A little saline in the syringe allows any occluding skin plug to be ejected. The vein is often located on withdrawal of the needle, since the friction of the large needle in the tissues can compress the internal jugular vein.
7	Disconnect the syringe from the needle, immediately occluding the open needle hub to prevent air embolism.	Do not move the needle at all! Keep the hand holding the needle in contact with the patient’s skin to prevent movement.
8	Insert the guidewire through the introducer needle and into the vein.	Do not move the needle! Do not force the guidewire—it should pass easily!
9	Advance the guidewire into the vein to the desired depth or until ventricular ectopy is seen on the ECG monitor.	The guidewire must be securely in the vein, not just in the subcutaneous tissue.
10	Withdraw the introducer needle a few millimeters and use the scalpel to enlarge the puncture site slightly.	Keeping the needle in place eliminates any possibility of cutting the guidewire.
11	Remove the introducer needle.	Never let go of the guidewire!
12	Thread the dilator over the guidewire until it can be grasped outside the hub, and then insert and withdraw the dilator.	Always keep a firm grip on the guidewire!
13	Thread the catheter tip over the guidewire and withdraw the guidewire from the skin until it can be grasped at the infusion hub.	Never let go of the guidewire.
14	Insert the catheter to the desired depth; most catheters are marked in centimeters, with larger markings every 5 and 10 cm. Introducer sheaths should be inserted completely.	The tip of the catheter should be in the superior vena cava, at the level of the manubriosternal angle.
15	Holding the catheter in place, remove the guidewire. Occlude the open hub with a gloved finger to prevent air embolism.	Do not apply excessive force to the guidewire. If it is trapped, withdraw the catheter a few centimeters and try again. Do not break the wire!
16	Attach a syringe to the catheter hub and aspirate blood, taking samples as desired; then flush the lumen with saline and begin the desired venous infusion.	Other lumens may be aspirated, flushed, and clamped.
17	Verify intravenous placement before suturing the catheter in place.	If the patient’s blood travels up the intravenous tubing, the catheter is in the carotid artery!
18	Remove the patient from the Trendelenburg position.	Take care not to puncture the catheter or to occlude it with a tight suture.
19	Suture the catheter to the skin with sutures and tape.	
20	Apply a dressing to the catheter site.	
21	Verify catheter tip position by chest radiograph.	Catheter tip must be in the superior vena cava, not in the right atrium. Tip should be above the azygos vein and the carina, with the tip parallel to the vessel wall.

*The central approach to the internal jugular vein is used as an example, although the same technique is used for other approaches and central veins.

the guidewire, rotate it slightly, and readvance it. **The use of force will kink the guidewire and may cause it to damage the vein and adjoining tissues.** Advance the guidewire 5 to 10 cm into the vessel or until ectopic beats are seen on the cardiac monitor. **Do not advance the guidewire more than 16 cm into the right internal jugular vein and 18 cm into left internal jugular or subclavian veins.**

Withdraw the introducer needle and guidewire sheath while securely holding the guidewire (**Figure 63-10C**). Grasp the guidewire with the nondominant hand as soon as the guidewire is visible between the tip of the introducer needle and the skin. Finish removing the needle over the guidewire.

Make a small incision in the skin adjacent to the guidewire using a #11 scalpel blade (**Figure 63-10D**). Place the dilator over the straight end of the guidewire (**Figure 63-10E**). Advance the dilator over the guidewire, through the skin, and into the vein. A slight twisting motion of the dilator as it is advanced may aid in its insertion. Continue to advance the dilator until its hub is against the skin. **Do not release hold of the guidewire at any time.** Remove the dilator over the guidewire.

Place the catheter tip over the guidewire. Advance the catheter over the guidewire and into the vein to the desired depth (**Figure 63-10F**). **Do not release hold of the guidewire.** Gently

rolling or twisting the catheter between the thumb and forefinger may aid in its advancement. Insert the catheter to the predetermined desired depth. This is approximately 16 to 18 cm for right-sided lines and 18 to 20 cm for left-sided lines. Hold the catheter securely in place and remove the guidewire (**Figure 63-10G**). Occlude the open catheter lumen with a sterile-gloved finger to prevent an air embolism and excessive blood loss.

Attach a syringe to the catheter hub and aspirate blood to confirm that the catheter is within the vein. Withdraw any necessary blood samples from the catheter. Remove the syringe. Attach infusion tubing or a heparin lock to the port and flush the catheter to prevent a blood clot from obstructing the lumen. If a multilumen catheter is inserted, flush any other lumens after first withdrawing any air (**Figure 63-13**). Securely attach the catheter to the skin with nylon or silk sutures. Cover the skin puncture site with a sterile dressing.

ANTERIOR APPROACH TO THE INTERNAL JUGULAR VEIN

The skin puncture site is at the anterior border of the sternal head of the sternocleidomastoid muscle, just lateral to the carotid artery and at the level of the cricoid cartilage (**Figure 63-5**). Enter the skin at a

FIGURE 63-10. The Seldinger technique. **A.** The vein is punctured by the introducer needle, and blood is aspirated. **B.** The syringe has been removed. The guidewire is inserted through the introducer needle and into the vein. **C.** The introducer needle and guidewire sleeve are withdrawn over the guidewire. **D.** The skin puncture site is enlarged. **E.** The dilator is advanced over the guidewire until the hub is against the skin; then it is removed. **F.** The catheter is advanced over the guidewire and into the vein. **G.** The guidewire is withdrawn through the catheter.

45° to 60° angle. Direct the introducer needle toward the ipsilateral nipple. **The internal jugular vein in an adult should be encountered within 3 to 5 cm of the skin.** If the vein is not encountered by 5 cm, withdraw the tip of the introducer needle to the subcutaneous space and redirect it slightly medially. The remainder of the procedure is as described for the central approach and in **Table 63-6**.

POSTERIOR APPROACH TO THE INTERNAL JUGULAR VEIN

Enter the skin at the posterior edge of the sternocleidomastoid muscle, one-third of the way from the clavicle to the mastoid process (**Figure 63-6**). Alternatively, the point where the external jugular vein crosses the lateral border of the sternocleidomastoid muscle can be used. Direct the introducer needle under the sternocleidomastoid muscle at a 30° to 45° angle to the skin and toward the sternal notch. Place the index finger of the nondominant hand in the

sternal notch to provide a landmark with the patient draped. **The internal jugular vein should be encountered within 5 cm from the skin. This approach is not recommended in children.** The remainder of the procedure is as described for the central approach and in **Table 63-6**.

NOVEL AND EMERGING APPROACHES TO THE INTERNAL JUGULAR VEIN

The sternocleidomastoid muscle and the carotid artery are the most commonly used landmarks for internal jugular vein catheterization. These landmarks can be difficult to palpate in certain patient populations. The sternocleidomastoid muscle can be obscure in unconscious or anesthetized patients and the carotid artery pulse is weak in hypotensive or arrhythmic patients. Other landmarks that are often more easily palpated may be ideal when classic external landmarks are difficult to identify.

FIGURE 63-13. Aspiration and flushing of catheters. **A.** Any air in the lumen of the tubing is aspirated into the syringe of flush solution. The syringe must be held upright, as shown. **B.** Stop aspirating once all the air is removed from the catheter and blood begins to enter the syringe. **C.** Flush solution is injected until the lumen is filled and contains no blood. This usually requires 2 to 4 mL of flush solution.

A method using the cricoid cartilage and external jugular vein as landmarks resulted in a 99% success rate in right internal jugular vein catheterization, an average of 1.75 attempts, and no carotid artery puncture.⁵⁶ Respiratory jugular venodilation in mechanically ventilated patients could be favorably used as the primary landmark for right internal jugular vein catheterization.⁵⁷ A modified anterior approach in pediatric patients uses the cannulation needle inserted along the anterior border of the sternocleidomastoid muscle at the level of hyoid bone.⁵⁸ A peripheral IV catheter (i.e., angiocatheter) can be placed with or without a guidewire inserted in the angiocatheter and the Seldinger technique.⁵⁹⁻⁶¹ The guidewire in an angiocatheter is faster and safer than the traditional Seldinger technique with US guidance.⁶² This may be useful in emergencies.

TABLE 63-7 Comparison of Subclavian Vein Cannulation Routes

	Infraclavicular approach	Supraclavicular approach
Entry site	Just inferior to the clavicle at the midclavicular line	1 cm lateral to the clavicular head of the sternocleidomastoid muscle, 1 cm posterior to the clavicle
Needle orientation	Keep as close to the coronal plane as possible	Tip aimed 10° anterior to the coronal plane
Needle bevel and “J” wire directed	Medially and caudally	Medially
Aim toward	Just posterior to the sternal notch	Contralateral nipple, needle bisects angle formed by the clavicle and the clavicular head of the sternocleidomastoid muscle
Distance from skin to subclavian vein	3–4 cm	2–3 cm

SUBCLAVIAN VEIN CATHETERIZATION TECHNIQUES

The technique is identical to that described above for internal jugular vein cannulation except for the puncture site. Two techniques, infraclavicular and supraclavicular, are described below and summarized in **Table 63-7**.

INFRACLAVICULAR APPROACH TO THE SUBCLAVIAN VEIN

The infraclavicular approach to the subclavian vein is most often used. It is commonly thought to be easier to perform and less likely to result in a pneumothorax than the supraclavicular approach, although data for this belief are lacking in adult and pediatric populations.⁶³⁻⁶⁶ Some Emergency Physicians prefer not to use a finder needle for infraclavicular subclavian vein cannulation as there is no danger of penetrating the carotid artery. This also makes as few

needle passes near the pleura as possible to decrease the risk of an iatrogenic pneumothorax. Estimate the distance from the skin puncture site to the superior vena cava (i.e., the manubriosternal junction).

Several different skin entry sites are described in the literature. Some feel that the preferred entry site is 1 cm caudal to the junction of the medial and middle thirds of the clavicle. The subclavian vein lies just posterior to the clavicle at this site (**Figure 63-14**). The first rib lies between the pleural dome and the subclavian vein. Direct the introducer needle just superior and posterior to the suprasternal notch while staying as close to the frontal (i.e., coronal) plane as possible. The needle and syringe should be parallel to the bed (**Figure 63-14**). Place the nondominant index finger in the sternal notch to help guide placement (**Figure 63-14**).

Some Emergency Physicians prefer to enter the skin inferior to the clavicle at the deltopectoral groove, or the point just lateral to the midclavicular line along the inferior surface of the clavicle. This is the point where the skin may be maximally depressed. Direct the introducer needle parallel to the bed and toward the sternal notch. This entry site may make it easier to keep the introducer needle in the coronal plane. The distance before entering the subclavian vein is longer than in the preceding approach and the protection offered by the first rib is lost.

One additional landmark can be used to identify the skin puncture site. Palpate the bony tubercle, or protrusion, on the inferior surface of the clavicle and approximately one-third to one-half the length of the clavicle from the sternoclavicular joint. The advantage of this site is that it is a definitive landmark and avoids approximating distances, as described for the other sites above. Insert the introducer needle parallel to the bed and aimed just posterior to the sternal notch.

Orient the bevel of the introducer needle caudally, as with the “J” in the guidewire (**Figure 63-15**).⁶⁷ This position will allow the guidewire to enter the innominate vein and superior vena cava rather than being directed upward into the internal jugular vein or across to the contralateral subclavian vein (**Figure 63-15**).⁶⁷ Manual

FIGURE 63-14. Infraclavicular approach to subclavian vein cannulation. **A.** Frontal (oblique) view of the procedure. **B.** Sagittal section through the medial third of the clavicle. Note the proximity of the pleura and subclavian artery.

FIGURE 63-15. Introducer needle bevel orientation for subclavian vein cannulation. Varying the orientation of the introducer needle bevel for infraclavicular and supraclavicular techniques helps guide the “J”-shaped guidewire into the superior vena cava.

occlusion of the internal jugular vein by compression just above to the clavicle prevents misplacement of the catheter in the internal jugular vein.⁶⁸ The Seldinger technique for catheter insertion is otherwise the same as previously described for internal jugular vein cannulation. Aspiration of bright red blood under pressure indicates subclavian artery puncture, which will be incompressible. Remove

the introducer needle and observe the patient for signs of significant hemorrhage over the next several hours. Aspiration of air indicates penetration of the pleura. Observation with serial chest radiographs for at least 6 to 24 hours is essential to evaluate the size of the resulting pneumothorax.

SUPRACLAVICULAR APPROACH TO THE SUBCLAVIAN VEIN

The supraclavicular approach offers some distinct advantages.⁶⁹⁻⁷¹ The supraclavicular subclavian vein is closer to the skin. The route from a right-sided skin puncture site to the superior vena cava is more direct. It allows easier access to the superior vena cava while avoiding the hazards of a left-sided puncture (i.e., the thoracic duct). The skin entry site is more accessible during CPR and requires less interruption of external chest compressions.⁷² With experience, the complication rate for the supraclavicular approach is probably lower than that for the infraclavicular approach.^{63,69,73}

Estimate the distance from the skin puncture site to the superior vena cava to guide the catheter insertion depth. The skin is entered at a point 1 cm lateral to the lateral border of the clavicular head of the sternocleidomastoid muscle and 1 cm superior to the clavicle (**Figure 63-16**).⁷⁴ The introducer needle should bisect the angle formed by the clavicle and the lateral border of the sternocleidomastoid muscle (**Figure 63-16A**). Direct the introducer needle toward the contralateral nipple or a point just superior and posterior to the sternal notch. Orient the introducer needle bevel medially (**Figure 63-15**).⁶⁷ The subclavian vein should be entered within 2 to 3 cm in an adult. The length of catheter inserted will be 2 to 4 cm less than that for the infraclavicular approach.

Alternative skin entry sites and approaches have been described. Enter the skin 1 cm medially and 1 cm superiorly to the midpoint of the clavicle with the introducer needle directed toward the ipsilateral sternoclavicular joint.⁷⁵ The skin can be entered just posterior to the clavicle, at the junction of the medial and middle third of the

FIGURE 63-16. Supraclavicular approach to subclavian vein cannulation. **A.** The insertion point is 1 cm superior to the clavicle and 1 cm lateral to the border of the sternocleidomastoid muscle. Direct the introducer needle tip at a 45° angle to the transverse and sagittal planes and slightly anterior toward the contralateral nipple. **B.** Sagittal section through the medial third of the clavicle. Note that the introducer needle track must be directed anteriorly to avoid the subclavian artery and the dome of the pleura.

clavicle, with the introducer needle directed toward the ipsilateral sternoclavicular joint and parallel to the coronal plane.⁷⁶ This last approach is probably the simplest, although the study cited was performed on cadavers rather than live patients.

AXILLARY VEIN CATHETERIZATION TECHNIQUE

The axillary vein must be accessed using US guidance and not blindly using landmarks. Place the patient supine with their arm abducted in a comfortable position. One US study demonstrated no benefit of arm abduction in increasing axillary vein size or decreasing arteriovenous overlap.²¹ There is no change in size of the axillary vein with the Valsalva maneuver or the Trendelenburg position.⁷⁷ Locate the axillary vein using a high-frequency (i.e., 5 to 10 MHz) US transducer. Place the US transducer, with the marker pointing cephalad, just below the clavicle at approximately its middle third. Identify the axillary artery, axillary vein, and the pleura to obtain proper orientation. Manual compression and color flow Doppler can be used to differentiate between the vein and the artery. Follow the axillary vein laterally on the chest until its overlap with the artery is minimized and the pleura is out of the view of the transducer. Rotate the US transducer into a parallel orientation in respect to the axillary vein with the transducer marker toward you to obtain a long axis view of the axillary vein. Gently pivot the US transducer in a cephalad and caudal direction to clearly differentiate the axillary vein from the axillary artery. Slight movements of the transducer will alter the ultrasound image between the vein and artery. It is recommended to stabilize the US transducer by resting the distal forearm and wrist against the anterior chest. Note the depth of the vein to ensure that the central venous catheter needle will be able to puncture the vessel. The remaining details of the technique are as described in Chapter 64 on US-Guided Vascular Access.

FEMORAL VEIN CATHETERIZATION TECHNIQUE

This technique is often performed blind using landmarks. It can also be performed under US guidance and serves as another viable option for central venous catheterization during CPR and trauma resuscitations.^{78,79}

The use of an electrocardiogram monitor is still recommended even though the short guidewire may not reach the heart. Care must be taken if the patient has a preexisting left bundle branch block, as complete heart block may result if the guidewire or catheter enters the right ventricle.³⁹ Premeasuring from the insertion site to the xiphoid process will give the maximum depth of catheter insertion.

The introducer needle should enter the skin 2 to 4 cm inferior to the midpoint of the inguinal ligament and 1 cm medial to the femoral artery pulse (**Figure 63-17**). The introducer needle should enter the skin 1 to 2 cm inferior to the inguinal ligament and 0.5 cm medial to the femoral artery pulse in an infant or young child. The cannulation technique is as described previously for the internal jugular vein.

Two site-specific considerations deserve mention. The use of a finder needle is unnecessary since there are no vital structures in the area other than the femoral artery that is compressible if it is punctured. The introducer needle is directed at a 45° to 60° angle to the skin and parallel to the long axis of the thigh. Shallower angles may be necessary in very small and thin patients. **Use caution to avoid puncturing the posterior wall of the vein above the inguinal ligament as this can result in a retroperitoneal hemorrhage.**

ALTERNATIVE TECHNIQUES

USE OF THE SELDINGER-HUB INTRODUCER CATHETER

Some central venous access kits include a catheter-over-the-needle with a tapered hub that can be used in place of the thin-walled introducer needle. This technique has the advantage of allowing the introducer catheter to remain in place while venous placement is verified. It provides less likelihood of the vein being lost as the aspiration syringe is removed and the guidewire advanced. A guidewire advanced through the introducer catheter cannot become sheared off as when it is inserted through the needle.

The vein is entered with the catheter-over-the-needle assembly attached to an aspirating syringe as described previously. Once the flashback of blood is obtained, advance the catheter-over-the-needle 2 mm further into the vein. This will ensure that the tip of the introducer catheter is within the vein. Hold the hub of the needle securely. Advance the catheter into the vein until its hub is against

FIGURE 63-17. Femoral vein cannulation. The skin puncture site is 1 cm medial to the femoral artery pulse and 2 to 4 cm inferior to the inguinal ligament. Direct the introducer needle posteriorly at a 45° to 60° angle while aspirating.

the skin. Withdraw the needle. If necessary, the introducer catheter may be attached to a pressure transducer and the venous waveform verified to confirm venous rather than arterial placement. Blood gas measurements may also be performed. Advance the guidewire through the introducer catheter and into the vein. The remainder of the procedure is as previously described.

MULTIPLE-LUMEN CATHETERS

Remove the cap from the distal port's injection hub prior to skin puncture. It is usually marked "distal." The other lumens may be flushed with saline or heparin solution and recapped or left capped and flushed later (**Figure 63-13**). **Heparin concentrations no higher than 100 U/mL should be used to avoid temporarily anti-coagulating the patient.**⁸⁰

The introducer needle and guidewire are inserted as described previously. Place the multiple-lumen catheter tip over the guidewire. Advance the catheter until the guidewire emerges from the distal port hub (**Figure 63-18**). Insert the catheter to the desired depth. Remove the guidewire. Flush the distal lumen and connect it to the desired infusion. Aspirate and flush the other lumens with the desired solution if not done previously (**Figure 63-13**).

PERCUTANEOUS INTRODUCER SHEATH (CORDIS)

The insertion technique differs slightly from those described above (**Figure 63-19**). Locate the vein, insert the needle followed by the guidewire, and remove the needle, leaving the guidewire in place as described previously. Insert the plastic dilator into the lumen of the sheath. The entire assembly must be advanced over the guidewire as a unit rather than using separate dilation and insertion steps (**Figure 63-19C**). A correspondingly larger skin nick must be made with the scalpel, since the sheath is usually of larger diameter than a catheter. Advance the dilator-sheath unit over the guidewire (**Figure 63-19C**) and into the vein (**Figure 63-19D**). A twisting motion may aid in its advancement. Continue to advance the unit until the hub of the sheath is against the skin (**Figure 63-19E**). Remove the guidewire and dilator as a unit (**Figure 63-19E**). The remainder of the procedure is as described previously.

ULTRASOUND-GUIDED CENTRAL VENOUS ACCESS

The use of bedside US to guide central venous access is becoming more common. The availability of US, its low cost, portable units,

FIGURE 63-19. Inserting an introducer sheath. **A.** The sheath. **B.** The dilator. **C.** The dilator is inserted into the sheath and the unit is threaded over the guidewire. **D.** Advance the unit over the guidewire and into the vein using a twisting motion. **E.** The dilator and guidewire are removed as a unit, leaving the sheath in place.

and training during residency are making its use standard procedure for central venous line placement. Higher procedural quality, consistency, and lower complication rates support its increasing use. Refer to Chapter 64 for the complete details of US-guided vascular access.

FIGURE 63-18. Inserting a multiple-lumen catheter. The guidewire exits through the uncapped distal port. The proximal port(s) must be clamped or capped to prevent air embolism.

PEDIATRIC CONSIDERATIONS

The anterior or central approach to the internal jugular vein is preferred for children. Appropriate catheter sizes and lengths are shown in **Table 63-3**. The child must be sedated and immobilized prior to attempts at cannulation of the internal jugular or subclavian vein. The femoral vein is the vein of choice if central venous access is needed in a combative child who cannot be completely restrained. The patient need not be in Trendelenburg position, the consequences of a misdirected needle are less severe, and the procedure is less threatening as the face is not draped. A shallower angle of skin entry than in an adult is necessary to access the femoral vein. Enter the skin 1 to 2 cm inferior to the inguinal ligament and 0.5 mm medial to the femoral artery. Subclavian vein access in the small child can be difficult due to the anatomic relationships of the vessels as previously described. Despite this, the subclavian vein and the femoral vein can be safely and effectively accessed in children less than 1 year of age. The use of the frog leg position decreases the overlap of femoral vessels.^{28,30}

Several researchers evaluated methods of the depth of central venous lines in children. The size of the catheter is listed in **Table 63-8**. It can be inserted into the carina.^{81,82} The problem with this is that a chest radiograph is needed after the catheter is inserted. It was determined that the distance to the carina can be calculated.⁸² The sternal head of the right clavicle was labeled “point A.” The mid-point of the perpendicular line from “point A” to the line connecting the patient’s nipples was labeled “point B.” The insertion point was labeled as “point I.” The distance to insert the catheter was determined by the following formula: (I to A, in cm) + (A to B, in cm) – 0.5. This formula determined the correct catheter length to insert 95% of the time.

Others looked at the distance to insert the catheter. Insertion depth was calculated using the patient’s height in centimeters.⁸³ If the patient’s height was ≤ 100 cm, insertion depth (cm) = [height (cm) ÷ 10] – 1. If the patient’s height was > 100 cm, insertion depth (cm) = [height (cm) ÷ 10] – 2. These formulae resulted in the catheter being at the superior vena cava–right atrial junction 97% of the time.⁸³ The left internal jugular vein insertion depth (in cm) was calculated from $0.07 \times \text{height (cm)}$, and the left subclavian insertion depth (in cm) was calculated as $0.08 \times \text{height (cm)}$.⁸⁴ This predicted 98.5% of correctly located catheters. Another formula was calculated for patients between the height of 40 and 140 cm using the right internal jugular vein.⁸⁵ They correctly located the catheter position in 97.5% of patients using the formula $1.7 + (0.7 \times \text{height in cm})$.

Methods were developed to increase the success of cannulation in children. The use of US increased the likelihood of successful placement and at the correct depth.⁸⁶ The central line can be inserted through the external jugular vein with good success rates.⁸⁷

ASSESSMENT

Examine the patient. Examine the lung fields carefully to exclude a significant iatrogenic pneumothorax. Recheck the patient’s vital signs frequently after the procedure. Obtain a portable anteroposterior chest radiograph to verify line tip placement in the superior

vena cava and rule out an iatrogenic pneumothorax.^{88,89} Check the catheter site for hematoma formation or hemorrhage along the dilated catheter track. Control any hemorrhage with direct pressure.

US can be used to evaluate positioning. It can be used to evaluate guidewire position prior to dilation and insertion of the catheter.^{90,91} This is helpful if the guidewire is intraarterial so it is not dilated. US can be used after insertion to determine the presence or absence of an iatrogenic pneumothorax.⁹² Detection of an anterior pneumothorax in a supine patient has been shown to be more sensitive using US than plain radiographs.⁹²⁻⁹⁴ **The use of US does not negate the need to determine catheter location by plain radiographs, even though there is a growing base of literature that demonstrates the ability of US to detect the catheter tip location.**⁸⁸ US may be a useful tool when postprocedural chest radiographs are delayed or the patient suddenly decompensates during or immediately after central line placement. US can be used with or without bubbles during a saline flush to detect the flow out of the catheter tip and into the vessel.^{92,95,96}

Check the function of the catheter by aspiration and infusion through all ports. A proximal lumen may be extravascular if it fails to aspirate blood easily. A catheter may be exchanged over a guidewire if the distal tip of the catheter is intravascular. Do not attempt to advance the catheter once the guidewire has been removed.

Check the position of the catheter tip on the chest radiograph.^{96,97} The catheter must not be in the heart due to the risk that erosion through the thin right atrial wall will result in a pericardial hemorrhage and tamponade.^{98,99} Landmarks for an internal jugular or subclavian vein catheter tip include above the level of the carina, above the azygos vein, at the level of the right tracheobronchial angle, and at/above the manubriosternal junction. The tip of the catheter should be parallel to the vein to prevent erosion through the wall of the vein. The catheter may be used for IV infusion if it crosses over to the opposite subclavian vein and the patient cannot tolerate an attempt at repositioning. **Lines placed from the subclavian vein into the jugular system must be replaced. Catheters in the right atrium must be pulled back immediately to prevent any arrhythmias and perforation of the myocardium.**

It is important to ensure that the catheter is within a vein and not an artery. The aspiration of dark blood and absence of pulsatile flow from the syringe hub at the time of line insertion confirms its located within a vein. Confirmation of line placement can be accomplished by US (Chapter 64), blood gas measurement, and/or pressure transduction. An arterial line monitoring set-up can be attached to the catheter to measure intravascular pressures but can be time consuming and expensive.

One alternative mode of pressure transduction is the Compass Vascular Access pressure measurement device (Mirador Biomedical, Seattle, WA).¹⁰⁰ This disposable, single patient use, digital manometer attaches between the syringe and introducer needle to rapidly provide a digital pressure measurement of the vasculature at the location of the needle tip (**Figure 63-20**). It can be used to provide pressure measurements while the guidewire is being inserted through the needle.

Most femoral vein catheters can be fully inserted. Premeasurement is recommended to make sure that the catheter tip will not reach the right atrium. Obtain postprocedural abdominal and chest radiographs if there is any doubt about the catheter position. The tip of the catheter must be at or below the xiphoid process of the sternum. Reassess the distal neurovascular status of the lower extremity after line placement.

AFTERCARE

The catheter must be sutured in place to prevent malpositioning of the line (**Figure 63-21**).¹⁰¹ Tie a surgeon’s knot at the skin and then secure the suture to the hole(s) provided in the catheter wings. The

straight needle contained within most central venous access kits can be difficult to use and poses a needle-stick risk (**Figure 63-22**). One option is to use nylon suture on a curved needle and a laceration repair kit. This requires additional equipment at an additional cost.

FIGURE 63-22. Using a straight needle with the finger can result in a needle stick. (Used with permission from reference 102.)

Another option is to use a needle cap or syringe contained within the kit to protect against the advancing straight needle puncturing a finger (**Figures 63-23, 63-24, and 63-25**).^{102,103} Use the cap to apply counter pressure against the skin as the straight needle tip exits the skin. A catheter clamp is often provided in the central line kit for longer catheters. It too should be sutured in place. The clamp holds the catheter in place by friction. It is not a guarantee that the catheter will not move. **Catheter depth should be checked daily by inspection and frequent chest radiographs.** Movement of the patient's head and neck may move the tip of the internal jugular vein catheter by as much as 4 cm.¹⁰⁴

An alternate method to secure the central venous catheter is using a SecureAcath (Interrad Medical, Plymouth, MN). This device

attaches to the skin-catheter junction (**Figure 63-26**). The device minimizes catheter movement and prevents needlesticks. It is quick to use, no sutures are required, and the catheter can be repositioned if inserted too deep. The SecureAcath allows cleaning the access site and keeps the catheter securely positioned during the cleaning.

Introducer sheaths have large lumens and present a significant risk of causing an air embolism. Cap the main lumen if it is not being used for an infusion. Any built-in diaphragm is not a reliable means of preventing an air embolism.¹⁰⁵ **Do not use the dilator as an occluder or infusion port, as the stiff plastic can easily erode through the wall of the vein.** An occlusive dressing can be used if no occluder is available.

Check the skin puncture site regularly for signs of infection. Cellulitis or purulent drainage requires a new central venous line at another site. Restrain any patient who is uncooperative to prevent inadvertent removal of the central line.

While the short-term infection rate of femoral lines compares favorably with that of other central venous line location sites, some precautions are necessary to prevent soiling.^{25,106} Consider the judicious use of bladder catheterization in patients incontinent of urine and rectal tubes in patients with loose stools. Patients with

percutaneous femoral vein catheters must be confined to bed to prevent catheter dislodgment and hemorrhage around the catheter. **Frequent assessment for venous thrombosis in the lower extremity is essential.**¹⁰⁷

REMOVAL OF THE CENTRAL VENOUS CATHETER

It has been, and sometimes still is, routine policy in some institutions to change all central venous lines placed in the Emergency Department when the patient arrives in the Intensive Care Unit. It was believed that these lines placed in the Emergency Department were “dirty” and at a higher risk of infection. This practice results in the additional time, cost, associated patient discomfort, and the potential for complications associated with a repeat procedure. The infection rate of central venous lines placed in the Emergency Department using aseptic technique were no different than those placed in the Intensive Care Unit.¹⁰⁸

Place the patient in the Trendelenburg position when removing a central venous catheter from the internal jugular or subclavian vein. Place the patient supine to remove a femoral vein catheter. Remove the dressing overlying the skin puncture site. Cut the suture securing the catheter to the skin. Ask the patient to exhale and hold their breath. Briskly remove the catheter and cover the puncture site with a gauze dressing. The track from the skin surface to the vein can be a source of a fatal venous air embolism.¹⁰⁹ Apply an occlusive dressing to the site for the first 1 to 2 days after the catheter has been removed. Observe the skin puncture site for signs of an infection twice a day for 48 hours.

COMPLICATIONS

Central line complications usually cause pain to the patient (i.e., from the complication or the resolution procedures). Central line complications are terrifying for patients, bothersome to the Emergency Physician, and costly for the facility. **Table 63-9** lists the risk factors for central venous line complications. Complications can be minimized by following some general rules (**Table 63-10**)

Mechanical complications can occur.¹¹⁰ The needle and/or guidewire may puncture the lateral or posterior wall of the vein. This can result in a hematoma formation, arterial puncture, arterial cannulation, and an arteriovenous fistula.¹¹¹ The catheter can cause atrial thrombi that may become infected.¹¹²⁻¹¹⁴ A catheter in the heart can result in a perforation and cardiac tamponade.^{89,115-117} A thrombus can form on the catheter that may eventually embolize to the lungs.¹¹⁸⁻¹²⁰ Catheters that abut the vein wall can erode through with time.¹²¹ The catheter tip can be malpositioned in a vein that connects to the vena cava.¹²²

The use of US guidance reduces but does not eliminate these complications.¹²³⁻¹²⁸ The guidewire or catheter can become lost, break, fragment, or become knotted intravascularly.¹²⁹⁻¹³¹ The guidewire can become a venous embolus if it completely enters the vein.¹³²⁻¹³⁸ The tip of the catheter can cause arrhythmias if it is located within the heart.¹³⁹⁻¹⁴¹

The guidewire can become caught on an inferior vena cava filter.¹⁴²⁻¹⁴⁵ This commonly occurs with guidewires inserted through

TABLE 63-10 Ways to Avoid Central Venous Line Complications

Access central line catheters sterilely and with sterile devices
Adhere to aseptic technique
Always use full sterile barrier precautions
Apply a sterile dressing to the skin puncture site
Avoid the central line placement
Attempt a US-guided peripheral IV line
Cleanse the central line port immediately before use
Perform skin antisepsis and allow this to dry before starting the procedure
Replace soiled dressings at the skin insertion site using aseptic technique
Remove the central line as soon as it is no longer needed
US-guided peripheral IV placement can eliminate the need for a central line
Use a central line insertion checklist to make fewer mistakes
Use an insertion checklist to allow ED personnel to adhere to the proper care techniques
Use a central line only when indicated
Use a central line when alternative options have been unsuccessful
Use hand hygiene before the procedure
Use US to place a central line to decrease complications
Select the optimal insertion site

a femoral vein. It can happen from internal jugular and subclavian vein guidewires that are inserted too far. An inferior vena cava filter is the only reason to consider using the straight end of the guidewire. **Stop moving the guidewire if any resistance is felt. Do not use any force to remove the guidewire.** Tape the guidewire to the patient so it does not further enter the patient and obtain an abdominal radiograph. Try to advance the entrapped guidewire to disengage it from the filter. Consult an Interventional Radiologist for removal under fluoroscopy. Overinsertion of the guidewire can dislodge an inferior vena cava filter. Avoid complications with inferior vena cava filters by inserting the guidewire a small distance (e.g., 10 cm)

Antibiotic-coated catheters have been developed and used.¹⁴⁶⁻¹⁴⁸ Their use is controversial. The catheters reduce line infections and sepsis. The evidence in children is mostly extrapolated from studies of adults. There is a question regarding whether they result in antibiotic-resistant organisms. They can expose patients to unnecessary antibiotics, can cause allergic reactions, and are more expensive to use. Leave these catheters for use by consultants to insert in the Intensive Care Unit, hospital floor, or as an outpatient for long-term therapy. The infection rate of uncoated catheters is lowest in subclavian lines followed by femoral and internal jugular lines.¹⁴⁹

INTERNAL JUGULAR VEIN CATHETERIZATION

Internal jugular venous access has a myriad of potential complications.¹¹⁰ Some of them are listed above. Infection can be either local at the site of insertion or systemic (i.e., bacteremia and sepsis). A pneumothorax can occur during line placement. A hemothorax may be life-threatening, especially if a venopleural fistula is created. A chylothorax occurs if the thoracic duct is lacerated. Airway compromise can occur due to the formation of a hematoma and compression of the airway. An air embolism can occur if the catheter lumens are left open to the air during insertion, if connections loosen and separate later, or if air enters the system while tube manometry is being used for line confirmation.^{150,151} Right ventricular irritation from the catheter tip can cause cardiac dysrhythmias. Puncture of the right atrial wall can lead to pericardial tamponade and death. Malposition of the needle and guidewire can rupture the cuff of an endotracheal tube.¹⁵² The guidewire can become entrapped and require surgical or interventional radiology removal. Embolization of the guidewire or catheter parts occurs with improper use of the equipment. Anaphylactic reactions to antibiotic-impregnated catheters have been reported.¹⁵³ The cardiac monitors should be observed during the procedure to prevent

the death of a critically ill patient from being unnoticed while the catheter is being inserted. Thrombosis of the catheter or vein may lead to pulmonary embolism.

Carotid artery puncture can occur while accessing the vein. It may be complicated by a stroke if the blood supply to the brain is interrupted or if a plaque embolizes. Devastating complications may result if arterial puncture is unrecognized and a large-bore dilator and/or catheter is then inserted arterially. **Do not remove the catheter if arterial dilation or cannulation accidentally occurs.** Consult a Vascular Surgeon for consideration of surgical or endovascular treatment to minimize risk of major complications (e.g., hemorrhage, major stroke, arteriovenous fistula).¹⁵⁴

Many of these complications can be prevented or minimized with the use of US guidance. US guidance resulted in lower rates of arterial puncture, hematoma formation, hemothorax, pneumothorax, and infection.¹⁵⁵ Multiple smaller studies have shown similar results in favor of US guidance.^{2,156-160} A comprehensive review published in 2015 reported a 71% reduction in overall complications with US guidance compared to a landmark technique.¹⁶¹ There is no specific report of complication rates involving the thoracic duct, nerve injury, or thyroid injury. This is likely due to the extremely rare incidence of damage to these structures. **US guidance has been shown to significantly reduce complications and improve patient safety for internal jugular vein access.** Complications during catheterization occur in proportion to inexperience.¹⁶² The most experienced person available should perform the procedure if the patient is unlikely to survive a mistake. The left jugular vein is smaller than the right and may account for more complications.⁷

SUBCLAVIAN VEIN CATHETERIZATION

Potential complications of subclavian vein cannulation are similar to those of internal jugular vein cannulation. There is minimal risk of carotid artery injury if the procedure is performed correctly. The pericardium, subclavian artery, or pulmonary vessels can be lacerated if the needle is advanced too deeply.^{111,163-166} Malposition of the catheter tip, usually due to overinsertion of the catheter, is common. Lacerations of the thoracic duct can be avoided by performing the procedure on the right side, avoiding overpenetration with the introducer needle, and avoiding directing the needle too superiorly toward the junction of the subclavian vein and internal jugular vein.¹⁶⁷ Other complications (e.g., injury to the brachial plexus and phrenic nerve) are uncommon but possible.^{111,168-170} They can be prevented by avoiding overinsertion of the needle during the

procedure and avoiding needle paths superior and posterior to the subclavian vein.

A pneumothorax is a very real risk with subclavian vein catheterization.^{164,171} **The procedure should not be performed unless personnel are immediately available who can deal with this complication.**¹⁷² The risk of a pneumothorax is probably higher in obese patients who may have distorted anatomic landmarks, and a more acute angle is required to enter the subclavian vein. Patients with emphysema may have higher pleural domes and less pulmonary reserve in the event of a pneumothorax.

Subclavian vein cannulation results in fewer complications when performed with US guidance. Higher rates of hematoma formation, hemothorax, pneumothorax, brachial plexus injury, phrenic nerve injury, and cardiac tamponade are seen with the use of the landmark technique when compared to US guidance.¹⁷³ Multiple meta-analyses showed lower rates of arterial puncture, hematoma formation, and pneumothorax with US guidance.^{174,175} Current evidence cannot elucidate whether the infraclavicular or supraclavicular approach to subclavian vein cannulation is safer.¹⁷⁶

FEMORAL VEIN CATHETERIZATION

Deep venous thrombosis of the femoral and more distal veins is a recognized complication of femoral venous lines (**Figure 63-27**).^{107,177-179} Inadvertent cannulation of the femoral artery may occur. This is particularly true during an episode of severe hypotension or cardiac arrest. Infusion of vasopressors into the artery may result in ischemic injury to the distal limb if an episode goes unrecognized.

Early studies suggested a higher risk of catheter-related bloodstream infections associated with the femoral vein cannulation compared to the internal jugular and subclavian sites. Recent studies demonstrate no significant difference in the infection rate between the three sites.^{33,177,178,180}

US guidance for femoral vein cannulation does not currently have large studies with robust data in the literature. Anatomic visualization can be useful in multiple situations. There is a trend toward fewer adverse events with US guidance.^{181,182} A meta-analysis showed better first-attempt and overall success at femoral vein cannulation with US guidance but did not demonstrate a difference in rates of complications.¹⁷⁵ The anatomic variation and overlap between the femoral artery and the femoral vein in normal patients brings to question the safety of blind or landmark-based venous cannulation.²⁹ US guidance may aid in identifying a very small femoral vein and/or significant arteriovenous overlap in a stable patient with a palpable

FIGURE 63-27. Ultrasound of a femoral deep venous thrombosis. (Photo courtesy of Lloyd Gordon, MD.)

pulse.²⁹ Correction with reverse Trendelenburg or proper leg positioning under US guidance may allow the Emergency Physician a better target for cannulation and reduce complications. Palpation of the femoral artery may not be feasible during periods of severe hypotension or cardiac arrest. This can lead to failed access or arterial cannulation. A higher rate of success and decreased rate of arterial cannulation was shown with US guidance during CPR.¹⁸³ US guidance for femoral vein cannulation may not yet be a standard practice but may be a useful technique that can reduce the complications.

SUMMARY

Central venous access is often necessary in critically ill patients and in those with poor peripheral veins. Mastery of these techniques is essential for anyone caring for acutely ill and unstable patients. While all approaches to the central circulation have acceptably low complication rates, they all carry real risks to the patient.¹¹⁰ Be certain that there is no peripheral access alternative before placing a central venous line.

The internal jugular vein is a good choice for central venous access in nonambulatory patients. The right internal jugular vein provides easy access to the superior vena cava for monitoring and for infusion of solutions too concentrated or irritating for peripheral veins. This route poses a slightly lower risk of complications than the subclavian route when done with landmarks.^{162,184}

The subclavian vein provides easy access to the central circulation. Subclavian vein catheters are more easily tolerated by awake and ambulatory patients than are internal jugular or femoral catheters. Subclavian vein cannulation does present very real risks to the patient that must be balanced against the need for the procedure. Subclavian vein access is the least preferred route in young children due to their small size, the proximity of the pleura, and the proximity of the subclavian artery.

Femoral vein cannulation is an essential emergency skill. It allows the easiest central venous access in most patients with the lowest risk of catastrophic immediate complications compared to jugular and subclavian access procedures.

US guidance for central venous access has rapidly become integrated into the practice of Emergency Medicine. Familiarity with US guidance has become a mandatory skill for the Emergency Physician when placing central venous lines.

Srikar Adhikari and Lori Stolz

INTRODUCTION

Central venous catheterization (CVC) is essential in the management of critically ill patients seen in the Emergency Department (ED). It allows for administration of vasoactive medications, central venous pressure monitoring, fluid resuscitation, and pacemaker placement. Complications (e.g., air embolism, arterial puncture, hematoma, hemothorax, and pneumothorax) have been reported to occur in 5% to 20% of patients.¹⁻³ Unsuccessful CVC has been reported in up to 20% of cases.^{4,5} **CVC has traditionally been performed using surface anatomic landmarks as a guide to locate the veins.** CVC is not always successful using the landmark method due to anatomic variations or obscured landmarks. Factors (e.g., congenital deformities, dehydration, intravenous drug abuse, obesity, scarring, shock, and thromboses) can complicate the procedure. Ultrasound (US)-guided vascular access is widely supported in current medical practice. The use of US guidance for CVC has been endorsed by several medical societies and supported by numerous clinical trials in the literature. **US guidance has been shown to improve CVC success rates, reduce mean insertion attempts, and reduce placement failure rates.**⁶⁻¹⁵ US guidance allows the

Emergency Physician to more precisely locate target vessels and provide real-time visualization of needle placement.

Peripheral venous access is more commonly performed in the ED than CVC. Patients lack easily located peripheral venous sites in many cases (e.g., chronic kidney disease, intravenous drug abuse, obesity, organ transplantation, and vascular disease). Obtaining peripheral intravenous (IV) access in these patients can be a challenge, even for the most experienced medical personnel. Multiple studies have shown that US-guided peripheral IV access is safe and successful in these patients.¹⁶⁻²² US-guided peripheral IV access prevents the need for CVC and the pain of multiple needle sticks in many “hard-to-stick” patients.²³

ANATOMY AND PATHOPHYSIOLOGY

It is important to recognize the differences in sonographic appearance between arteries and veins to perform US-guided vascular access. Arteries and veins can be distinguished by their ability to be compressed, Doppler mode signal, location, shape, size, and spectral Doppler waveforms. Arteries have relatively thick and hyperechoic (i.e., white) walls and anechoic (i.e., black) lumens. Veins have relatively thin and hypoechoic (i.e., gray) walls and anechoic (i.e., black) lumens. The thin-walled veins are usually easily compressible, have no pulsations on Doppler mode, and are oval-shaped (**Figures 64-1 and 64-2**). Arteries are typically round in appearance and pulsatile on Doppler mode (**Figures 64-1 and 64-2**). **Arteries and veins are often found adjacent to each other.** Veins are usually larger in diameter than arteries in a well-hydrated patient (**Figure 64-1**). The anatomy relevant to the sonographic evaluation of central and peripheral veins is described in the following sections.

CENTRAL VEINS

The internal jugular, subclavian, and femoral veins are commonly used for US-guided CVC. The internal jugular vein traverses the neck and is unopposed by bone. This makes it an ideal vein to visualize with US. The internal jugular vein lies underneath the bifurcation of the sternal and clavicular heads of the sternocleidomastoid muscle. It continues to run vertically downward in the neck. It lies at first lateral to the internal carotid artery and then lateral to the common carotid artery (**Figure 64-1**). It eventually joins the subclavian vein.

The subclavian vein lies anterior to the subclavian artery along a course from the lateral border of the first rib to the medial border of the anterior scalene muscle. It joins the internal jugular vein medially to form the brachiocephalic vein. Subclavian vein cannulation is technically more challenging because it runs for a

FIGURE 64-1. US image of the neck vessels. The internal jugular vein (IJV) is thin-walled and oval. The carotid artery (CA) is thick-walled and round.

FIGURE 64-2. The US transducer is used to apply external pressure to the soft tissues of the neck. The internal jugular vein (IJV) collapses with gentle compression. CA, carotid artery; SCM, sternocleidomastoid muscle.

significant distance under the clavicle, which produces a large acoustic shadow. Cannulation is most frequently performed from an infraclavicular approach and just lateral to the clavicle at the intersection of the axillary vein and subclavian vein (**Figure 64-3**). This approach allows visualization of the vein without the acoustic shadowing of the clavicle and a greater distance from the pleura.

The common femoral vein lies medial to the common femoral artery and inferior to the inguinal ligament. The superficial femoral and deep femoral veins join in the upper thigh to form the common femoral vein. The greater saphenous vein joins the anteromedial aspect of the common femoral vein below the inguinal ligament (**Figure 64-4**). The common femoral vein changes its name to become the external iliac vein after it passes under the inguinal ligament.

PERIPHERAL VEINS

The three veins of the upper extremity that are most commonly used for US-guided vascular access are the basilic, brachial, and cephalic veins. The venous drainage of the upper extremity

FIGURE 64-3. US image of the right axillary vein. The US transducer is placed in the right infraclavicular region.

FIGURE 64-4. Transverse US image of the femoral vessels. The common femoral vein (CFV) lies medial to the common femoral artery (CFA). The superficially located greater saphenous vein (GSV) enters the common femoral vein 2 to 3 cm below the inguinal ligament.

consists of a deep system and a superficial system. The deep system includes radial and ulnar veins in the forearm that unite to form the brachial vein, the deep vein in the upper arm. The brachial vein lies next to the noncompressible and pulsatile brachial artery (**Figure 64-5**) and median nerve. It is not uncommon to find paired superficial and deep brachial veins (**Figure 64-5**). The two major superficial veins of the upper arm are the basilic and cephalic veins. The basilic vein begins in the ulnar side of the dorsal hand venous network, ascends along medial aspect of forearm and upper arm, and joins with the brachial veins to form the axillary vein. The cephalic vein arises from the radial aspect of the dorsal hand venous network, ascends proximally along the anterior border of the brachioradialis muscle, runs lateral to biceps muscle, and terminates in the axillary vein.

The great saphenous vein can be accessed in the lower extremity using US guidance. The vein runs along the medial aspect of the lower extremity, anterior to the medial malleolus of the ankle, and posterior to the medial epicondyle of the femur. The saphenous vein can be cannulated anywhere along its course. It is most commonly accessed just proximal to the ankle (**Figure 64-6**).

STATIC APPROACH TO VASCULAR ACCESS

The static approach to vascular access involves confirming the location of the vessel prior to performing the cannulation. Place the US transducer perpendicular to the skin to visualize the vessel

FIGURE 64-5. Transverse US view of the upper arm veins. BA, brachial artery; BAV, basilic vein; BV, paired brachial veins.

FIGURE 64-6. Transverse US view of the saphenous vein (SV) above the ankle.

and verify compressibility. Adjust the transducer so that the target vessel is in the center of the US monitor screen. **This puts the vessel directly under the center of the US transducer.** Place a mark on the skin at the midpoint of the US transducer to mark the vessel location. Repeat this process to assess the path of the vessel at a point 2 cm away and along the vessel. **Marking these two points on the skin will serve as a guide to direct the needle or catheter-over-the-needle. Determine how deep the vessel is located.** Look at the depth markers on the side of the US monitor screen. Remove the transducer and prepare the patient.

Proceed with the catheterization. Insert the needle or catheter-over-the-needle approximately 0.5 cm above or below the skin mark. Advance and direct it to the appropriate depth underneath the skin markings. **The patient must be reimaged and the skin markings repeated prior to inserting the needle or catheter-over-the-needle if the patient changes position after marking the skin but before needle puncture.** The advantages of the static approach are its simplicity and that the US transducer does not need to be prepared for the sterile portion of the procedure. The disadvantage of this technique is that the needle is not visualized in real time while performing the procedure.

DYNAMIC APPROACH FOR VASCULAR ACCESS

The dynamic approach to vascular access involves inserting the needle or catheter-over-the-needle into the vein under real-time US guidance. Three techniques are used for the dynamic approach.^{24,25} They refer to the orientation of the US transducer and target vein during the venipuncture. The short axis approach visualizes the vessel in a cross section. The long axis approach visualizes the vessel longitudinally. The oblique approach visualizes the vessel at an oblique angle.

Each approach has its own advantages and disadvantages. The short axis approach provides better medial to lateral orientation of the needle or catheter-over-the-needle in relation to the target vessel and allows for visualization of adjacent structures in the same image. Novice sonographers can learn the short axis approach more quickly, and it can be performed in anatomic locations where space is limited (e.g., the groin or neck in an obese patient). One potential danger with the short axis approach is unseen penetration of the posterior wall of the target vessel and adjacent structures. The long axis approach allows better depth and needle or catheter-over-the-needle slope information. The entire needle or catheter-over-the-needle can be tracked with this approach.²⁶ The

long axis approach provides much better visualization of the tip of the needle and its trajectory, thus avoiding inadvertent puncture of the posterior wall of the vessel. The long axis approach requires more hand-eye coordination and is technically more difficult to learn. The oblique approach is a hybrid between transverse and longitudinal approaches. The transducer is placed at an oblique angle to the vessel. The needle or catheter-over-the-needle is advanced toward the vessel in-plane with the US transducer. The advantage of this approach is the ability to visualize structures adjacent to the target vessel and observe the needle tip continuously throughout the procedure. The disadvantage is that the needle contacts the vessel at an oblique angle, and this technique may be more difficult to learn.²⁷

INDICATIONS

US can be used to mark the site of needle entry or provide real-time guidance.

Use US guidance for all CVCs if the equipment is available. Use US for peripheral IV access in all “hard-to-stick” patients, in children, when a peripheral vein is not visible, or when a peripheral vein is not palpable.²⁸⁻³⁴ The use of US-guided peripheral IV access in the patient with difficult peripheral IV access can prevent the need for CVC.^{35,36} It is highly recommended in patients with anticoagulant use, in children, and in patients with coagulopathies, disseminated intravascular coagulation, a history of difficult IV access, hypotension, IV drug abuse, obesity, poor anatomic landmarks, prior surgical interventions or radiation in the area, scarring on the skin above veins, severe dehydration, or thrombocytopenia.³⁷⁻³⁹

CONTRAINDICATIONS

There are no absolute contraindications to the use of US for central or peripheral venous access except lack of US training and experience.

EQUIPMENT

- US machine
- US gel
- High-frequency (5 to 10 MHz) linear array US transducer
- Sterile US transducer cover (i.e., clear plastic cover or sterile glove, sterile US gel, and rubber bands)
- Povidone iodine or chlorhexidine solution
- Equipment for peripheral IV access (Chapters 59 and 61)
- Equipment for CVC (Chapter 63)
- Water-soluble lubricant, sterile
- Translucent dressing (e.g., Tegaderm)
- 2 to 3 inch long catheter-over-the-needle (i.e., angiocatheter), various sizes

PATIENT PREPARATION

CENTRAL VENOUS ACCESS

Position the patient the same as if performing CVC using the landmark method (**Figure 64-7**). Place the US machine across from where standing and in a direct line of sight to minimize the body movement required to view the US image. Stand at the head of the patient with the US machine at the patient's hips for internal jugular vein access (**Figure 64-7A**). Place the patient in the Trendelenburg position with their head turned to the contralateral side or kept in a neutral head position (**Figure 64-7A**). The relationship of the internal jugular vein to the carotid artery changes with head position. **The internal jugular vein assumes a more lateral position to the carotid artery in the neutral position.⁴⁰ This minimizes the risk of arterial puncture while accessing the target vein.⁴¹** The right internal jugular vein is easier to find and cannulate due to its

D

increased size.^{42,43} The use of shoulder rolls decreases the overlap of the internal jugular vein and carotid artery.⁴⁴ Place the patient in the Trendelenburg position with the shoulders and head in a neutral position for subclavian vein access. Position the US machine on the contralateral side of the patient from the Emergency Physician (Figures 64-7B and 64-7C). Caudal traction of the ipsilateral arm may assist in exposure of the subclavian vein for a supraclavicular approach.^{45,46} Abduction of the arm to 90° can improve visualization of vessels for the infraclavicular approach.^{47,48} Stand at the bedside adjacent to the patient's hip with the US machine above the patient's shoulder for femoral vein access (Figure 64-7D). Place the patient in reverse Trendelenburg with their hip abducted and externally rotated (Figure 64-7D). This position may enhance the success rate

of catheterization by decreasing the overlap with the femoral artery, increasing the surface area of the femoral vein, and increasing the vein diameter.⁴⁹⁻⁵³

Perform a preliminary US scan prior to preparing the patient for the sterile procedure. Survey the underlying vasculature to confirm the patency of the target vein, determine the optimal site for venipuncture, and adjust the US machine settings to optimize the image. The ability of the vein to be compressed distinguishes an artery from a vein, confirms the patency of the vein, and reduces the risk of cannulating a thrombosed vein (Figure 64-8). **Do not assess compressibility in the long axis.** The US transducer may slide off the vein and the vein lumen disappears, misinterpreting the vein as being compressible. Clean and prep the skin at the access

FIGURE 64-8. A clot or thrombus in the femoral vein. The image on the left is labeled on the right. (Courtesy of Lloyd Gordon, MD.)

site as if performing a traditional CVC. Prepare the US transducer as discussed below. **Follow strict aseptic technique and all barrier precautions during the procedure.**

The procedure can be performed by either one person (i.e., the Emergency Physician) or two people (i.e., the Emergency Physician and an assistant). The assistant stabilizes the US transducer over the vein, and the Emergency Physician performs the procedure using the two-person technique.

ULTRASOUND TRANSDUCER PREPARATION

A high frequency (i.e., 5 to 10 MHz) linear array US transducer is typically used for US-guided vascular access. **These US transducers produce linear images and are ideal for visualization of**

superficial structures such as veins. Always use a sterile US transducer cover and sterile US gel when performing CVC. Set up a sterile field on a bedside table. Open the US transducer cover set onto the sterile field.

Instruct an assistant to hold the US transducer upright and place standard or sterile US gel on the footprint of the US transducer (**Figure 64-9A**). Apply the sterile transducer cover over the US transducer using aseptic technique (**Figure 64-9B**). **Smooth all the air bubbles away from the footprint of the US transducer to prevent imaging artifacts.** Secure the cover with rubber bands to prevent it from sliding off the US transducer (**Figure 64-9C**). Place the US transducer on the sterile field (**Figure 64-9D**). Apply sterile US gel onto the cover over the transducer footprint just before scanning.

FIGURE 64-10. The US transducer marker and the marker on the US machine screen are aimed in the same direction.

ULTRASOUND TRANSDUCER ORIENTATION

The marker on the US transducer and the marker on the US machine screen should be aimed in the same direction in the short axis approach (**Figure 64-10**). The needle moves to the right on the US machine screen if it moves to the right side of the US transducer. This helps to accurately move the needle right to left while directing the needle toward the vein. This makes performing the procedure less complicated. It is important to know which way the transducer marker is directed in the long axis or oblique approach so that the Emergency Physician knows which side of the screen the needle will come from (i.e., the right or left of the image) (**Figure 64-11**).

IDENTIFICATION OF VEINS

Identify and verify the depth, direction, and patency of the vein prior to the procedure. Place the US transducer in the triangle formed by the two heads of sternocleidomastoid muscle and clavicle to locate the internal jugular vein (**Figure 64-12A**). Scan from the apex of the triangle to the clavicle. Visualize the internal jugular vein, carotid artery, and thyroid gland (**Figure 64-12B**). The internal jugular vein is an irregular and oval-shaped structure lateral to the carotid artery

FIGURE 64-11. Long axis approach for internal jugular vein access. Note transducer indicator and needle.

B

C

FIGURE 64-12. Identification of the internal jugular vein. **A.** Patient and US transducer positioning. **B.** The transverse or short axis view in B-mode. **C.** Short axis view in color Doppler mode. The large blue internal jugular vein (IJV) is clearly visible adjacent to the red carotid artery (CA). SCM, sternocleidomastoid muscle.

(**Figures 64-12B and 64-12C**). Visualize the internal jugular vein and identify its widest diameter, the depth from the skin surface, and its relationship to the carotid artery. Instruct the patient to perform a Valsalva maneuver to increase venous flow and distend the internal jugular vein while observing the US machine screen to note the changes in the US appearance of the vein.

Identify the vein using US. The subclavian vein can be cannulated using the infraclavicular or supraclavicular approach.⁵⁴ The supraclavicular approach has some advantages (i.e., can be performed simultaneously with cardiopulmonary resuscitation or tube thoracotomies, decreased risk of arterial puncture, decreased risk of pleura puncture, larger target, more direct path to the superior vena cava, shorter skin to vein distance, and well-defined landmarks). Place the US transducer inferior and lateral to the midportion of the clavicle to locate the subclavian vein using the infraclavicular approach (**Figure 64-13**). The clavicle and first rib are identified by a hyperechoic line with an acoustic shadow (**Figure 64-13B**). Visualize the subclavian and axillary veins in the short axis view. Position the target vein in the middle of the screen and rotate the transducer,

A

B

maintaining visualization of the vein until a long axis view is obtained. This maneuver enables visualization of axillary vein, distal subclavian vein, and the pleura underneath the vessels. The pleura is seen just deep to the vein and is identified by a hyperechoic line with associated sliding movement, characteristic of pleural sliding (**Figure 64-13B**). It might be difficult to demonstrate compressibility due to the slightly deeper location of the veins. Use Doppler to confirm the appropriate vessel (**Figure 64-13C**). Trace the internal jugular vein caudally into the supraclavicular fossa and locate the confluence of the internal jugular vein and subclavian vein using the supraclavicular approach (**Figure 64-14A**). Angle the transducer from a posterior to anterior position to locate the subclavian vein, which lies anterior to the subclavian artery (**Figure 64-14B**). Use an endocavity transducer with a smaller footprint instead of a linear array transducer if there is limited space in the supraclavicular area.

Scan below the midpoint of inguinal ligament to locate the common femoral vein (**Figure 64-15A**). The common femoral artery is visible next to the common femoral vein (**Figure 64-15B**). The greater saphenous vein merges with the common femoral vein on the medial aspect. Visualize the common femoral vein and identify its widest diameter, the most superficial location, the depth from the skin surface, and a location that does not overlap with the common femoral artery.

Do not apply excessive pressure with the US transducer when assessing the vein. Excessive pressure can collapse the vein and makes it difficult to identify. Verify that the identified vessel is compressible and truly a vein. **The ability of the vein to be compressed distinguishes artery from vein, confirms the patency of the vein, and reduces the risk of cannulating a thrombosed vein. Do not assess vein compressibility in the long axis.** The US transducer may slide off the vein and the vein lumen will disappear, misinterpreting the vein as being compressible.

Doppler can be used to identify vascular structures. Color Doppler ensures the patency of blood vessels (**Figure 64-12C**). Spectral Doppler distinguishes blood flow patterns. Spectral Doppler demonstrates respiratory phasicity in the femoral veins and biphasic flow patterns in the internal jugular and subclavian veins because of their proximity to the heart (**Figure 64-16A**). Triphasic pulsatile flow is seen on spectral Doppler of the femoral and subclavian arteries, and low resistance flow is seen in the common carotid artery (**Figure 64-16B**).

TECHNIQUES

SHORT AXIS APPROACH TO CENTRAL VENOUS ACCESS

The short axis approach allows visualization of the vein in cross section. This view is obtained by placing the US transducer perpendicular to the long axis of the vein. The vein appears oval-shaped in this view (**Figures 64-1, 64-12B, and 64-15B**). Place sterile US

A

B

FIGURE 64-15. Identification of the common femoral vein. **A.** Patient and US transducer positioning. **B.** Transverse or short axis view in B-mode. CFA, common femoral artery; CFV, common femoral vein.

gel on the skin above the vein and on the footprint of the sterile US transducer. Grasp the US transducer with the nondominant hand and the needle or catheter-over-the-needle with the dominant hand. Reidentify the vein and the optimal site of insertion. **Determine the best location to puncture the vein in relation to the adjacent artery by assessing the percentage of posterior free wall of the vein in contact with the artery (Figure 64-17).** Adjust the US transducer to center the target vein on the US machine screen. The midpoint of the US transducer now becomes the reference point for needle insertion.

Select the skin entry site to maximize the chances that the tip of the needle punctures the vein and intersects the US transducer scan plane. The geometry of the Pythagorean Theorem (i.e., $a^2 + b^2 = c^2$) can be used to assess the distance to insert the needle into the skin and away from the US transducer (Figure 64-18). Measure the distance from the skin surface to the center of the vein. This distance is equal to the distance from the transducer to where the needle punctures the skin at a 45° angle. For example, if the distance from the skin surface to the center of the vein is 1 cm, make the skin puncture 1 cm from the midpoint of the US transducer along the trajectory of the vein (Figures 64-18A and 64-18B). Insert and advance the needle at a 45° angle. The vein will then be punctured after the needle is inserted 1.4 cm. **It is very useful to assess the distances using this method before venipuncture to avoid complications.** Reassess the needle trajectory if the vein is not punctured within the expected inserted needle length.

The US beam is very narrow and only 1 to 2 mm wide despite the US transducer being approximately 1 cm wide. The needle will be visualized only when it is within this narrow beam. The cross section of the needle in the short axis approach will be seen only when it crosses the US scan plane that is oriented perpendicular to the needle. The needle tip or shaft will appear as a hyperechoic dot within the vein (Figure 64-19A). It will be seen in association with either an acoustic shadow (i.e., black) or a reverberation or ring down artifact (i.e., white echoes) posterior to the needle (Figure 64-19B).

Clean, prep, and anesthetize the skin after estimating the distance to the vein. Insert and advance the needle at a 45° angle (Figure 64-20). **The needle location can only be identified by signs of it pushing through the tissue as soft tissue movement during the initial portion of the needle path.** This is because the needle has not yet crossed the US transducer scan plane. Small, rapid, and in-line movements of the needle are helpful to locate the needle tip on the US image. **Do not mistake the needle shaft for the needle tip.** Always try to locate the needle tip by angling or fanning the US transducer. The needle will tent or buckle the vein wall as it contacts the anterior vein wall (Figure 64-21). **The wall of the vein will first collapse downward as it is being punctured and then return to normal after the wall is punctured.** Visualize the hyperechoic needle tip within the lumen of the vein to confirm the needle entered the vein (Figure 64-19A). A concurrent flash of blood will be seen in the syringe. Place the US

FIGURE 64-22. The long axis orientation and needle insertion.

transducer back onto the sterile field. The remainder of the procedure is as described for the landmark technique of CVC (Chapter 63).

LONG AXIS APPROACH TO CENTRAL VENOUS ACCESS

The long axis approach targets the vein along its length in the longitudinal plane (Figure 64-22). Grasp the US transducer in the nondominant hand and the needle with the dominant hand. Locate the target vein using the short axis approach. Verify it is compressible. Slowly rotate the US transducer to visualize the vein in the long axis. The US transducer should be positioned directly over the vein so that its long axis is parallel to the long axis of the vein (Figure 64-22). Adjust the US transducer to visualize the vein at its greatest anteroposterior diameter.

Insert the needle through the skin at approximately a 30° angle adjacent to one end of the US transducer (Figures 64-22 and 64-23).

FIGURE 64-23. The long axis approach for venous access.

FIGURE 64-24. Long axis view of the needle shaft in the subcutaneous tissues and the tip inside the lumen of the vein.

The needle should be in the plane that is in-line with the long axis of the US transducer and in the exact same plane as the US beam. **Keep the US transducer steady and over the vein with this approach.** Advance the needle. The needle tip and shaft will be visualized in real time as it travels through the subcutaneous tissues and into the lumen of the target vein (Figure 64-24). The needle plane and US transducer scan plane are not aligned if the needle is not visualized in the US image. Do not advance the needle any further. Withdraw the needle toward the skin and redirect it to align it with the US beam and the long axis of the vein.

OBLIQUE APPROACH TO CENTRAL VENOUS ACCESS

The oblique approach allows visualization of the structures that are adjacent to the target vessel and full needle-tip evaluation throughout the procedure. This approach combines the advantages of the long and short axis approaches. It may allow a higher first-pass success rate and decrease the complications compared to other approaches.²⁵ The oblique approach is not commonly used and may be difficult to learn.

Place the US transducer on the skin above the target vessel and identify the vein in the short axis. Confirm that the vein is compressible. Rotate the transducer approximately 45° to almost mid-way between the short and long axis views (Figure 64-25A). The vein will be visualized as oval-shaped (Figure 64-25B). Insert the needle into the skin on one end of the US transducer in-plane with the US beam. The needle tip and needle shaft will be fully visualized as the needle travels at an oblique angle toward the target vessel. Stop advancing the needle if the needle tip is not visualized. Retract the needle and realign it with the US beam. The needle will enter the vessel at a 45° angle. **Do not continue to advance the needle once it is within the vessel walls.** When using a Seldinger technique, the guidewire will be threaded through the needle and will be required to advance along this angle. This may complicate the procedure.

PERIPHERAL VENOUS ACCESS

Place the patient supine with their upper extremity abducted to expose the anteromedial aspect of the upper arm (Figure 64-26). Place a tourniquet on the upper arm and just below the axilla to distend the veins.⁵⁵ Do not use a blood pressure cuff as a tourniquet.⁵⁵ Sit or stand facing the patient. Position the US machine so that the

FIGURE 64-25. The oblique approach for venous access. **A.** The transducer is rotated almost midway between the short and long axis views. **B.** Ovoid appearance of the vein using the oblique approach (right). The view can be compared to the short axis (left).

screen is easily visible (**Figure 64-26**). Scan the entire upper arm from just below the tourniquet to the elbow to locate the veins and find the ideal venipuncture site. Identify the basilic vein along the medial aspect of the upper arm (**Figure 64-27**). Move the US transducer slightly laterally to visualize the brachial vein adjacent to the brachial artery. Scanning further laterally will identify the cephalic vein. Place the tourniquet at the calf with patient supine to locate the saphenous vein (**Figure 64-28**).

Place the transducer anterior and superior to the medial malleolus to locate the saphenous vein (**Figure 64-28**). This location has been successfully used in children.^{56,57} The saphenous vein in

children less than 3 years of age is bigger than hand and forearm veins and equal in size to the antecubital vein.

Peripheral veins collapse very easily. Minimize the pressure placed upon the skin surface with the US transducer. **Too much pressure can collapse these veins and make them difficult to identify.** Identify the segment of vein that is widest in diameter, closest to the skin surface, and not adjacent to an artery or nerve. Verify that the vein is compressible and patent as described previously.

Prepare the skin insertion site. There is no need to follow any special precautions (e.g., a sterile US transducer cover). Apply a large transparent dressing (e.g., Tegaderm) onto the footprint of the linear array US transducer (**Figure 64-29**).⁵⁸ **Make sure that no air bubbles are trapped between the transparent dressing and the**

FIGURE 64-26. Patient and US machine positioning for upper extremity peripheral venous access.

FIGURE 64-27. Short axis US image of the basilic and brachial veins. BA, brachial artery; BAV, basilic vein; BV, brachial vein.

FIGURE 64-28. US transducer positioning for saphenous venous access. (Used with permission from reference 56.)

US transducer. The transparent dressing keeps the field sterile and prevents contamination of the US transducer with blood. Use water-soluble lubricant (e.g., Surgilube) instead of US gel for scanning. Use a 2.5 to 3.0 inch long catheter-over-the-needle for US-guided peripheral IV access. Standard-length peripheral IV catheters are too short to reach or stay within the lumen of the vein. Identify the vein in the long axis (**Figure 64-30A**), short axis (**Figure 64-30B**), or oblique axis using the methods described previously. Insert the catheter-over-the-needle under US guidance. Advance the catheter-over-the-needle into the vein lumen (**Figure 64-31**). Put down the US transducer. Withdraw the needle, attach IV tubing onto the hub of the catheter, and secure the catheter.

ARTERIAL ACCESS

US guidance can be used to assist in obtaining an arterial blood gas and the placement of an arterial catheter in children and adults.^{24,59-64} Identify the artery by its round shape, relatively thick walls, noncompressibility, pulsatile contractions, and Doppler flow. The procedure

FIGURE 64-29. A sterile Tegaderm is used to cover the US transducer. (Used with permission from reference 58.)

A

B

of cannulating an artery is the same as described above for a vein. Refer to Chapter 72 for the complete details regarding arterial puncture and cannulation.

ASSESSMENT

Successful placement of venous access is traditionally confirmed by withdrawing venous blood, easy flushing of saline solution, and radiographs for CVC.⁶⁵ US can be used to confirm the catheter placement by scanning the length of the cannulated vein in the long axis and short axis views to visualize the catheter within the lumen of the vein (**Figure 64-31**).⁶⁶⁻⁶⁹ The advantages of US are that it can be performed at bedside and is quicker than radiographs.

Real-time visualization of a saline flush within the venous system can be used as an adjunct to confirm accurate catheter placement.⁷⁰ Saline flushed into the distal port of a central venous catheter can be visualized within the right atrium. Use the phased array or curvilinear US transducer to obtain a subxiphoid four-chamber image. Visualize the right heart using US and have an assistant flush 10 mL of agitated sterile saline through the distal port. Visualize punctate hyperechoic microbubbles from the flush within 2 seconds in the right atrium (**Figure 64-32**).⁷¹

A

B

FIGURE 64-31. Confirmation of venous catheter placement. **A.** Short axis view **B.** Long axis view.

The saline flush can be used for confirmation of peripheral venous catheters (**Figure 64-33**). Use a linear US transducer. Identify the tip of the venous catheter in the vein using the short or the long axis view. Advance the US transducer to visualize the area just beyond the tip of the catheter while flushing normal saline through the catheter. Hyperechoic microbubbles will be visualized in the vessel (**Figure 64-33**).

AFTERCARE

No specific aftercare is required following the US guidance. The aftercare procedures are related to the central venous line (Chapter 63) and peripheral IV (Chapters 59 and 61) placement.

COMPLICATIONS

Complications related to using US for vascular access are generally due to poor technique or misinterpretation of images. The inability to continuously visualize the needle tip during the procedure can result in inadvertent puncture of the adjacent artery or nerve. An artery can be misinterpreted as a vein. There is no exposure to

FIGURE 64-33. Flush test for confirming peripheral venous catheter placement. Hyperechoic microbubbles are seen in the vein leaving the tip of the catheter.

ionizing radiation. No increased risk of infections has been reported with the use of US when aseptic technique was followed. US guidance can be more time consuming when used for routine peripheral IV access. Its use may save time in the patient with difficult venous access. Using too short of a peripheral IV catheter can result in it being pulled out of the vein and the infusion solution extravasating.⁷² This can be prevented by using a longer (i.e., 2 to 3 inch) catheter-over-the-needle and/or inserting the catheter at a steeper angle to minimize the distance it travels in the subcutaneous tissues.

Use US to confirm the position of the central venous catheter. It can identify whether the central venous catheter is malpositioned by following the catheter's course. The catheter can go into the contralateral internal jugular vein instead of the superior vena cava (**Figure 64-34**). This requires changing it over a guidewire or inserting one at a different site. The catheter can be inserted too far and be located within the right atrium instead of the superior vena cava (**Figure 64-35**). Withdraw the catheter back slightly and repeat the imaging.

FIGURE 64-35. Malposition of the central venous catheter in the right atrium (arrow). Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Used with permission from reference 75.)

FUTURE CONSIDERATIONS

Many companies are planning or make a guidance system for central venous access.⁷³⁻⁷⁵ One popular device is the AxoTrack (Soma Access Systems, Greenville, SC). The AxoTrack is a US probe with a built-in needle guidance system (**Figure 64-36**). It incorporates real-time information of the needle direction and location. The needle is visualized from the skin puncture to the vein. It includes an US transducer with a needle guide. The transducer has magnetic

sensors, monitors needle depth and projects this on the US monitor screen. This allows the Emergency Physician to know the needle path and where the needle tip is located without adjusting the transducer. A clamping system secures and stabilizes the needle once inserted into the vessel.

SUMMARY

US-guided vascular access is widely supported in current clinical practice. It can be used for central and peripheral IV access. US guidance has been shown to reduce failure rates and many of the complications associated with the traditional landmark technique. The benefits of US guidance include precise localization of the target vein, visualization of adjacent structures, identification of anatomic

variations, avoidance of veins with thrombus, and real-time visualization of venipuncture. Knowledge of the US anatomy and basic US technology combined with hand-eye coordination are essential to perform this procedure. Understanding the principles discussed in this chapter will enhance the success rate of vascular access.

Troubleshooting Indwelling Central Venous Lines

James J. McCarthy

INTRODUCTION

Indwelling central venous lines are an essential part of the care of acute and chronically ill patients (**Figure 65-1**). These patients may require implanted venous access devices due to their poor peripheral venous access or for long-term intravenous therapies (**Figures 65-2 through 65-4**). **The Emergency Physician must act quickly and thoughtfully to diagnose and correct the malfunctioning indwelling central venous line without further damaging the device or exposing the patient to increased risk.** Understanding the various etiologies and a thorough assessment are critical to the successful management of a central venous catheter malfunction.

ANATOMY AND PATHOPHYSIOLOGY

Indwelling central venous catheters allow access to the central venous circulation from a peripheral site. This access to the central circulation is via the end of a partially implanted catheter that protrudes from the body or through the skin into a subcutaneous reservoir of a fully implanted catheter (**Figure 65-1**).^{1,2} The proximal tip of the central venous line resides in the inferior vena cava, the right

FIGURE 65-2. A Mahurkar short-term vascular access catheter. (Courtesy of Medtronic, Minneapolis, MN.)

FIGURE 65-1. A variety of indwelling access devices. (Courtesy of Smiths Medical, St. Paul, MN.)

FIGURE 65-3. Long-term vascular access catheters. **A.** The Eschelon. (Courtesy of Medical Components, Harleysville, PA.) **B.** The Groshong. (Courtesy of C.R. Bard, Murray Hill, NJ.)

atrium, or the superior vena cava. Distance from the right atrium is an important risk factor for catheter occlusion, with the incidence of occlusion increasing the more distal the catheter tip.³

Indwelling central venous access devices can malfunction for a variety of reasons. The two most common types of vascular catheter complications are thrombotic occlusions and infections.⁴ The etiology of the malfunction can be divided into external to the catheter and internal to the catheter. External malfunctions are, for the most part, mechanical malfunctions (e.g., catheter migration, the catheter tip abutting a vessel wall, a mural thrombus, and kinked catheters). Internal malfunctions can be divided into thrombotic (e.g., intraluminal thrombus, fibrin sheath, and fibrin tail) and nonthrombotic

(e.g., drug-drug precipitate, drug-solution precipitate, insoluble salts, and lipid precipitate).⁴⁻⁶ Phenytoin and diazepam cannot be given through silicone indwelling lines as they can crystallize and permanently obstruct the catheter lumen.⁵ Calcium and phosphate can form an insoluble precipitate within the catheter lumen. Other medications that can precipitate are etoposide, heparin, imipenem, oxacillin, ticarcillin, and vancomycin. Infused lipids can form waxy casts within the catheter lumen.

INDICATIONS

Any catheter that cannot be easily flushed or aspirated requires further investigation. Defer catheter troubleshooting to the Primary Care Provider if peripheral venous access is readily available and the patient is not acutely ill due to catheter sepsis or central venous thrombosis. **It is important to consider that delaying troubleshooting may make management more difficult and therefore necessitate line replacement.** The Emergency Physician will have to address the problem if emergent or urgent access to the patient's central vascular system is required.

CONTRAINDICATIONS

Do not inject or use any device that is obviously displaced from the central circulation as it is not salvageable. Dislodging a clot or septic thrombus from a catheter tip can lead to a fatal pulmonary embolism. Avoid catheter manipulation if signs of sepsis or central venous thrombosis are present.⁷ The use of indwelling dialysis lines for purposes other than dialysis is discouraged. **Only manipulate a dialysis line in a true emergency or if the line is malfunctioning and is needed for urgent hemodialysis.**

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile alcohol prep pads
- Thrombolytic agent
- Syringes, 5 mL and 10 mL
- 18 gauge needles
- Noncoring (i.e., Huber) needle
- 70% ethanol solution
- 0.1 N hydrochloric acid (HCl) solution
- Sterile saline

FIGURE 65-4. Subcutaneous buried ports. **A.** Examples. **B.** Access using the Huber needle. (Courtesy of Smiths Medical, St. Paul, MN.)

- Heparinized saline flush solution (100 U/mL)
- Sterile gauze squares
- Sterile gloves
- Sterile gown
- Face mask with an eye shield or goggles
- Cap
- Sterile towels or drapes

Repair kits are available to repair some externally damaged partially implanted catheters. The kits avoid the need to remove the device and implant a new catheter. Apply a smooth catheter clamp proximal to the damaged area and arrange to have the device repaired if the external tubing is damaged. The use of these kits is beyond the scope of this chapter.

THROMBOLYTIC AGENTS

The use of a specific thrombolytic agent is institution and physician specific. Streptokinase, recombinant tissue plasminogen activator (i.e., t-PA or alteplase), reteplase, and urokinase have all been successfully used to dissolve a clot within a central venous catheter.^{5,8-13} **Volumes and doses of the drugs differ significantly. Pay careful attention to the medication administration. Urokinase and recombinant tissue plasminogen activator are most commonly used.** Streptokinase is more likely to lead to a hypersensitivity reaction, especially if the patient has prior exposure to it, and is therefore not recommended. Urokinase is much less expensive than t-PA. Urokinase may be purchased in concentrations of 5000 U/mL and 250,000 U/5 mL (50,000 U/mL). The concentration of 5000 U/mL is used to dissolve a clot within a catheter.

Some institutions prefer to use t-PA for this process. The Pharmacist dilutes a 50 mg vial of t-PA with 50 mL of sterile water to produce 25 syringes containing 2 mg of t-PA in 2 mL (1 mg/mL). The syringes of t-PA are then frozen until needed. It is available from the manufacturer in 2 mg single-use vials and sold as Cathflo (Genentech, South San Francisco, CA). Alteplase or t-PA (i.e., Cathflo) is currently the only Food and Drug Administration-approved thrombolytic agent in the United States indicated for the restoration of function to central venous access devices.

Standard dosing for catheter obstructions is 1 mL of urokinase (5000 U/mL), 2 mL of t-PA (1 mg/mL), or 0.4 U of reteplase.¹⁴ The Groshong catheters (**Figure 65-3B**) have a slit valve at their proximal end that alleviates the need for heparin. Heparinized saline is used less often today in central venous lines due to heparin-induced thrombocytopenia.

PATIENT PREPARATION

Discuss the procedure with the patient and/or their representative. Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Most patients with indwelling central venous access devices are familiar with their use and idiosyncrasies. The patient will often be able to tell the Emergency Physician if the line has had problems in the past and the method used to correct the problem. Some patients will be able to suggest postural changes (e.g., raising an arm or lying in the Trendelenburg position) that will help the catheter function better.

The chest radiograph is a good screening tool that often allows the Emergency Physician to diagnose catheter complications. Obtain a posteroanterior and lateral chest radiograph to confirm that the tip of the catheter is in a proper location. Routine chest radiographs can be eliminated in pediatric oncologic patients with asymptomatic

occlusion due to their low diagnostic yield.¹⁵ **A malpositioned catheter or one with the tip abutting the vessel wall must be removed and replaced.** A catheter whose flow changes with patient arm position may be subject to the “pinch-off” phenomenon. This may be visible as a kinking of the catheter as it passes between the clavicle and first rib. A series of chest radiographs with the arm at the patient’s side and elevated may reveal the kinking or pinching-off of the catheter. These catheters require removal. A catheter may migrate intravascularly to the contralateral subclavian vein. An Interventional Radiologist may be able to insert a wire or snare into the femoral vein to grasp and reposition the catheter. Arrhythmias associated with a catheter tip positioned within the heart require the catheter to be removed and a new one inserted. The distal catheter can curve upward so that it lies within the jugular vein. An Interventional Radiologist may be able to reposition it. Otherwise, it must be removed and replaced.

Any aspiration, injection, or manipulation of a central venous line must be done using strict sterile techniques. Clean any blood, dirt, and debris from the distal port of a partially implanted device or the skin overlying the reservoir of a fully implanted device. Apply povidone iodine or chlorhexidine and allow it to dry. Wipe off the iodine (if used) with a sterile alcohol prep pad. **This process must be performed every time a needle is inserted into a central venous access device.**

TECHNIQUES

An algorithmic approach to the occluded indwelling central venous catheter is summarized in **Figure 65-5**.¹⁰ **Never perform forced irrigation of the catheter, especially with a 1 mL syringe, to prevent the catheter from rupturing.**

A catheter that flushes easily but cannot be aspirated may have a fibrin sheath around the catheter tip forming a one-way valve. The tip may also be lodged against the wall of the superior vena cava or the right atrium. Repositioning the patient may alleviate the problem. The catheter may be cautiously used for an infusion if there are no signs of infection (e.g., discharge at the catheter or subcutaneous reservoir site, erythema, fever, or a new heart murmur) and the catheter tip is in good position. Refer the patient to their Primary Care Provider or a consultant for follow-up of the malfunction.

The problem is more serious if the catheter does not easily flush. Attempt to obtain peripheral intravenous access while attempting to correct the problem with the central venous catheter. **The Emergency Physician must decide if a prolonged effort at resolving the occlusion is necessary if there are no signs of infection and the catheter is not ruptured or malpositioned.** If so, proceed as described below and in **Figure 65-5**.

PARTIALLY IMPLANTED CATHETERS

A clot or small amount of precipitate within the partially implanted catheter (**Figures 65-1 through 65-3**) may be able to be aspirated if the catheter bore is large enough to permit passage. Remove the Luer-lock cap from the catheter. Connect a 10 mL syringe with 2 to 3 mL of sterile saline directly to the occluded port’s Luer adapter. **Any clot large enough to occlude the catheter will not pass through a needle.** Apply negative pressure to the syringe. The catheter is probably occluded by a clot or a precipitate if the obstruction cannot be aspirated. Remove the syringe and attach a new Luer-lock cap.

Determine if a precipitate seen in the catheter aspirate is waxy or solid. Waxy precipitates are due to the lipid component of parenteral nutrition fluids. Waxy precipitates may be dissolved with a solution of 70% ethanol in water. Inject 1 to 2 mL of an alcohol-water solution and allow it to dwell in the catheter for 1 hour. Aspirate the catheter to determine patency. Inject 1 to 2 mL of 0.1 N hydrochloric acid

(HCl) solution if the catheter is still occluded. Allow the solution to dwell in the catheter for 20 minutes. Aspirate the catheter to determine patency. Attempt to infuse 0.1 N HCl solution two more times. The next step is to infuse a thrombolytic agent, as described below, or to replace the catheter.

Solid precipitates are due to precipitation of medications or minerals. Dilute HCl solution may be used to dissolve precipitated calcium and phosphate crystals. Infuse 1 to 2 mL of 0.1 N HCl and allow it to dwell in the catheter for 20 minutes. Aspirate the catheter to determine patency. The process may be repeated up to three times. Inject 1 to 2 mL of 70% ethanol in water and allow it to dwell in the catheter for 1 hour if it is still occluded after HCl administration. Aspirate the catheter to determine patency. The next step is to inject a thrombolytic agent, as described below, or to replace the catheter.

A clot may be present within the catheter lumen if no precipitate is present or if efforts to clear the precipitate fail. Clots probably form to some extent in most implanted central venous catheters. The clots may obstruct the catheter lumen partially or totally.¹⁶ Thrombosis of the central veins, superior vena cava, or right atrium may occur. Suspect a major vein thrombosis if there is swelling, pain, or edema of anatomic structures that are drained by the cannulated vein(s).

Small clots may be dissolved by a bolus or infusion of a thrombolytic agent. Inject 1 mL of urokinase (5000 U/mL), 2 mL of t-PA

(1 mg/mL), or 0.4 U of reteplase into the catheter. Allow the solution to dwell in the catheter for 30 minutes. Aspirate the catheter to determine patency. This process may be repeated up to three times. The medication dosing should remain the same but be divided into equal doses between the ports for catheters with multiple occluded ports. Inject 2 mL of intravenous contrast dye under fluoroscopy or inject the dye and obtain a radiograph if the catheter is still occluded after thrombolytic administration. Attempt to clear the catheter up to three times with HCl and 70% ethanol in water if no clot is present or if the contrast material will not infuse.

Consider a continuous thrombolytic infusion if a clot is present within the catheter. The infusion should occur through an intravenous line equipped with a 0.22 or 0.45 μ m filter. A urokinase infusion may be begun over a 24-hour period. Administer the urokinase at a dose of 200 U/kg/hour mixed to run at a rate of at least 20 mL/hour.^{9,10} A continuous t-PA infusion may also be started. Use 2 mg/20 mL as a low dose for ports, 4 mg/20 mL as a high dose for ports, or 5 mg/50 mL as a high dose for tunneled catheters. Set the t-PA infusion rate at 10 mL/hour for low and high doses for ports or 20 mL/hour for high-dose tunneled catheters. Perform thrombolytic infusions in consultation with the patient's Primary Care Provider as the patient will require hospital admission.

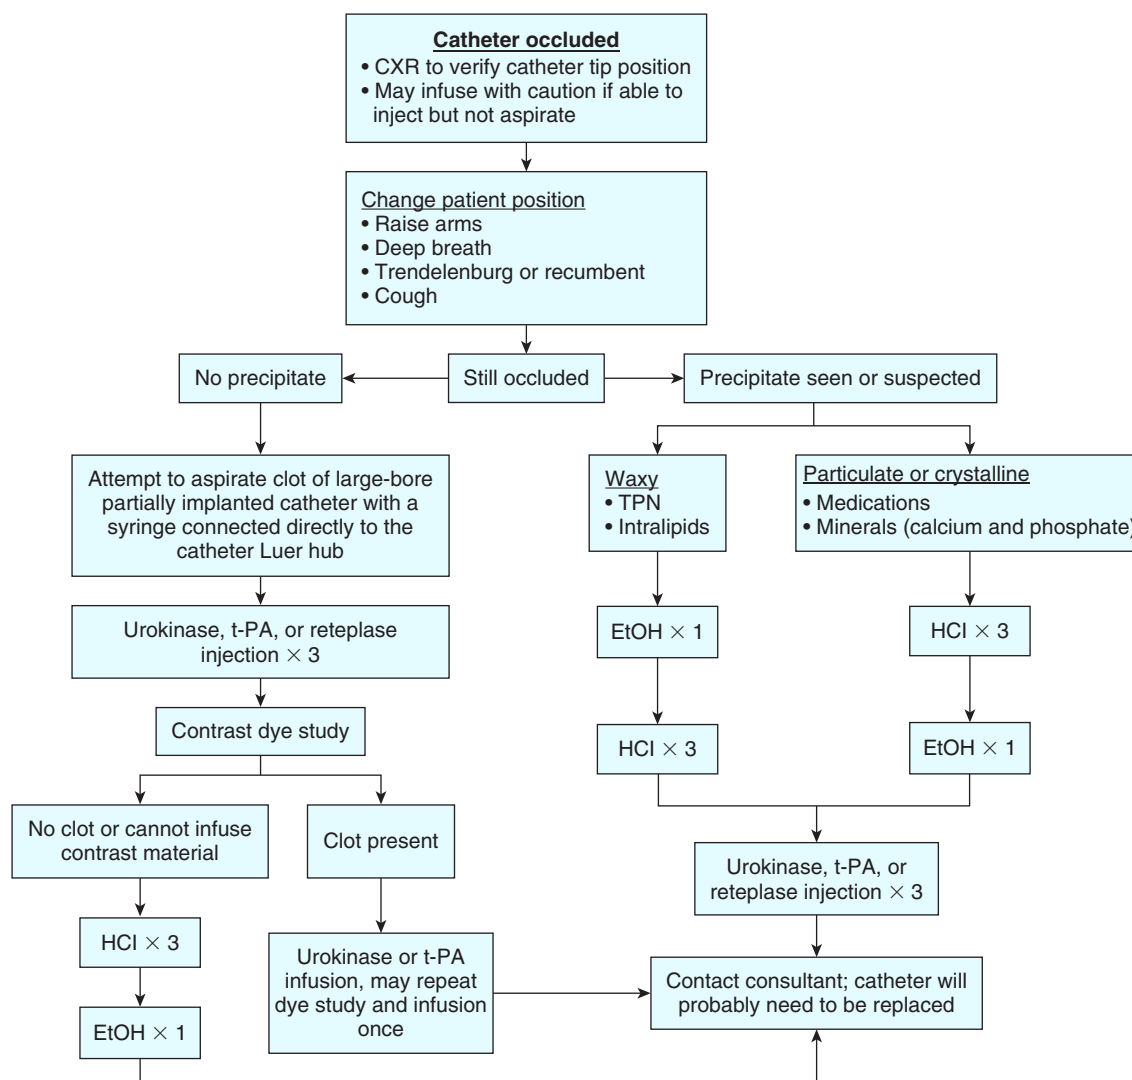

FIGURE 65-5. An algorithmic approach to the occluded central venous catheter. Continue to work down the protocol until the occlusion is resolved. CXR, chest radiograph; EtOH, 70% ethanol in water; HCl, 0.1 normal hydrochloric acid solution; TPN, total parenteral nutrition.

Consider consulting an Interventional Radiologist if these methods do not successfully clear the catheter or if a thrombolytic infusion is contraindicated. They can perform percutaneous fibrin sheath stripping, exchange the catheter over a wire, or remove and replace the malfunctioning catheter. Alternatively, the Emergency Physician may place a new central venous catheter at another site if the patient requires immediate vascular access.

FULLY IMPLANTED CATHETERS

The procedure is the same for a fully implanted central venous access device (Figure 65-4) with one exception. The subcutaneous reservoir will not be able to be initially cleared by aspiration. Any clot or precipitates large enough to occlude a catheter will not pass through a noncoring (Huber) needle. **Always use a noncoring (Huber) needle when aspirating or injecting through a fully implanted catheter (Figure 65-4B).**

AFTERCARE

Indwelling central venous lines must be flushed with saline. Do not use heparin solutions.^{17,18} Assess patients given thrombolytics for bleeding at the catheter site and elsewhere prior to discharge if they do not require hospital admission. The success rate for thrombolytics restoring catheter patency are greater than 80%.^{19,20} Admit patients receiving prolonged thrombolytic infusions for the infusion and for monitoring of potential bleeding complications. **Patients and their care providers must be made aware of any catheter malfunctions and the attempts made at restoring catheter patency.**

COMPLICATIONS

The complications associated with attempts to resolve an occluded catheter include catheter rupture, disconnection of the catheter from any implanted reservoir, hemorrhage, and contamination of the catheter with subsequent infection. No major bleeding episodes or deaths have been associated with intracatheter thrombolysis.^{14,19,20} Assessment for the complications associated with a central venous line is discussed in Chapter 63.

SUMMARY

Numerous patients with indwelling central venous access devices will present to the Emergency Department with malfunctioning catheters. Familiarity with the strategies for diagnosing and correcting the catheter dysfunction will enable the Emergency Physician to restore the function of some, but not all, indwelling lines. Early consultation with the Primary Care Provider, Vascular Surgeon, or Interventional Radiologist is essential if the procedures outlined do not promptly restore the catheter's function.

Accessing Indwelling Central Venous Lines

John Cruz and Chad Gorbakkin

INTRODUCTION

Venous access for blood sampling, hemodialysis, hydration, medication administration, and nutritional support is essential for the management of many chronic diseases.^{1,2} A variety of indwelling central venous access devices have been developed to avoid frequent venipunctures and permit direct access to the central circulation. Approximately 150 million intravascular devices are currently in use in the United States.³ These devices may be partially or completely embedded under the patient's skin (Figures 66-1 and 66-2). The Emergency Physician must be able to access these devices to administer medications and withdraw blood samples without causing catheter damage or catheter thrombosis. Familiarity with this process can be potentially lifesaving if the need for resuscitation becomes imminent in a patient with an indwelling line. The necessary procedures for successfully accessing indwelling devices are described in this chapter.

FIGURE 66-1. Indwelling central venous lines. **A.** The partially implanted central venous line. The distal end of the line emerges from the chest wall. Contamination of the implanted portion is prevented by a subcutaneous tunnel and a Dacron cuff around the catheter. **B.** The fully implanted central venous line. The catheter is connected to a reservoir that is contained in a subcutaneous pocket.

FIGURE 66-2. Indwelling subcutaneous fully implanted devices are used to access the body cavities and veins. (Courtesy of Smiths Medical, Dublin, OH.)

ANATOMY AND PATHOPHYSIOLOGY

Indwelling central venous lines allow access to the central venous circulation from a peripheral site.^{4,5} This is accomplished through the end of a partially implanted catheter or through the skin into a subcutaneous reservoir of a fully implanted catheter (**Figures 66-1 and 66-2**). The proximal tip of the central venous line may lie in the superior vena cava or in the right atrium. Catheters designed for right atrial placement are made of softer and more pliable material than catheters used for short-term transcutaneous central venous access. These catheters are less likely to erode through or perforate the thin wall of the right atrium or veins.

The internal jugular, subclavian, and femoral veins can all be used as a route for a central venous line to access the vena cava or right atrium. Subclavian veins are most commonly used to maximize patient comfort and mobility. The vein is punctured transcutaneously when the line is initially inserted. The catheter is inserted into the vein, and its distal segment is tunneled under the skin. The distal end of the catheter is pulled through a small puncture at the skin exit site if the line is partially implanted (**Figure 66-1A**). Its distal end is connected to a subcutaneous reservoir if the line is fully implanted (**Figures 66-1B and 66-2**).

PARTIALLY IMPLANTED CATHETERS

Partially implanted central venous catheters (**Figures 66-1A and 66-3**) are those in which the distal end emerges from the skin via a subcutaneous tunnel.⁶ This tunnel is designed to prevent the spread of skin flora along the outside of the catheter and ultimately toward the central circulation. Most partially implanted catheters use a subcutaneous Dacron cuff to further insulate the proximal catheter from skin flora and help anchor the catheter in place.⁷

A variety of models are in use, including the most commonly used Broviac, Hickman, and Groshong catheters.⁸⁻¹⁰ All are available in single-lumen or multiple-lumen versions. Broviac and Hickman catheters must be flushed with heparin solution twice weekly. The Broviac catheter is generally longer and thinner.⁴ The larger internal diameter of the Hickman catheter is designed to allow more frequent accessing without the risk of compromising line patency.⁴ The design of the Groshong catheter is unique in that it has a slit valve at its proximal end that prevents the reentry of blood once it has been flushed (**Figure 66-4**). Groshong catheters need only a weekly saline flush to prevent clot formation.

The Hemo-Cath or Perm-A-Cath is the largest bore of the right atrial catheters. It is used for chronic analgesia, hemodialysis, long-term nutritional support, and plasmapheresis. These catheters are typically flushed during dialysis. They are otherwise flushed three times per week with heparinized saline. See **Table 66-1** for review of recommended frequency and volume of flushes.

FULLY IMPLANTED CATHETERS

Fully implanted central venous catheters are entirely embedded and do not exit the skin (**Figures 66-1, 66-2, 66-5, and 66-6**). The catheter's distal end attaches to a subcutaneously implanted reservoir.⁷ Various catheters (e.g., Groshong and Hickman catheters) can be attached to a subcutaneous reservoir. Most fully implanted central venous access systems are known by the brand names (e.g., Infuse-A-Port and Port-A-Cath). Most manufacturers recommend flushing these catheters with a heparin solution monthly when not in use.¹⁰ Flushing of the port system can be done every 3 months without any increase in complications.¹⁰ The reservoir's infusion port is covered with a self-sealing silicone rubber membrane (**Figures 66-5 and 66-6**). **Specially designed noncoring Huber needles must be used when accessing the subcutaneous reservoir to avoid permanent fenestration of the self-sealing membrane (Figure 66-7).**

FIGURE 66-3. The partially implanted central venous catheter. **A.** An example of a dual-lumen catheter. (Courtesy of Medical Components Inc., Harleysville, PA.) **B.** A single-lumen catheter is shown schematically. The Dacron cuff lies in the subcutaneous tissue just proximal to the skin entry site. The catheter tip lies in either the proximal superior vena cava or the right atrium.

FIGURE 66-4. The Groshong catheter tip. Detail of the Groshong three-position slit valve that prevents venous blood from passively entering the catheter when it is not in use. **A.** The closed or resting position of the slit valve. **B.** The valve opens outward from positive pressure when the catheter is flushed or infused. **C.** The valve opens inward from negative pressure when the catheter is aspirated.

TABLE 66-1 Volumes and Concentrations of Heparin Flushes for Common Indwelling Catheter Devices in Adults		
Type of central line	Volume of recommended flush	Recommended frequency of flush
Broviac Catheter	3–5 mL of heparinized saline (100 U/mL)	After each use Twice per week
Groshong Catheter	5 mL of heparinized saline (100 U/mL)	After each use Once per week
Hemo-Cath/Perm-A-Cath	≤ 2 mL of heparinized saline (1000 U/mL)	After each use 3 times per week
Hickman Catheter	3–5 mL of heparinized saline (100 U/mL)	After each use Twice per week
Port-A-Cath/Infuse-A-Port	5 mL of heparinized saline (100 U/mL)	After each use Monthly

PERIPHERALLY INSERTED CENTRAL CATHETERS

Peripherally inserted central catheters (i.e., PICC lines, **Figure 66-2**, and **Chapter 62**) are inserted into the antecubital, brachial, or cephalic vein of the upper extremity and advanced into the subclavian vein. PICC lines are available in single- and double-lumen configurations based on the indication for placement. PICC lines are made of either silicone or polyurethane. They are 50 to 60 cm long and have an outside diameter of 2 to 7 French, with the 5 French being most commonly used. Some PICC catheters are equipped with a Dacron cuff. Advantages to PICC placement include their ability to be inserted in outpatient settings, ease of placement, ease

FIGURE 66-6. Accessing the fully implanted central venous catheter system. The reservoir is stabilized between the fingers of the nondominant hand as a noncoring (Huber) needle is used to penetrate the skin and reservoir.

of maintenance, and ultimately, removal upon cessation of the indication for which it was placed. The greatest drawback for the use of PICC lines is the variable rate of catheter-related upper extremity thrombosis. Greater than 50% thrombosis rates have been noted in patients receiving chemotherapy.¹¹

FIGURE 66-5. The fully implanted central venous catheter. **A.** The reservoir lies in the subcutaneous tissue and is anchored with sutures to keep the diaphragm facing the skin surface. **B.** An example of a single reservoir. **C.** An example of a dual reservoir. (Photos courtesy of Medical Components Inc., Harleysville, PA.)

FIGURE 66-7. The Huber needle. **A.** Photo of a complete right-angle Huber needle set including the extension tubing and clamp. **B.** Photo showing the right-angle Huber needle compared with a standard hypodermic needle. **C.** Drawing showing the key difference between a standard hypodermic needle and the Huber needle. The hypodermic needle tip can cut a cylindrical core of subcutaneous tissue and the diaphragm sealing the subcutaneous reservoir. The Huber needle pushes the subcutaneous tissue and the diaphragm material aside without removing any of it.

B

C

PERCUTANEOUS CENTRAL VENOUS CATHETER

A device similar to the PICC that is used exclusively in the neonate is the percutaneous central venous catheter (PCVC). This catheter is primarily used in the Neonatal Intensive Care Unit and is uncommonly encountered in the Emergency Department. PCVCs are often implanted for nutritional support in very-low-birth-weight infants, infants for whom feedings are contraindicated, and prolonged vascular access in critically ill patients.¹² They are available in three sizes (i.e., 1.1, 1.9, and 2.8 French). The 2.8 French size is used more often because the smaller sizes tend to become occluded with a thrombus. Accessing the device follows the same general principles outlined below. This includes adhering meticulously to aseptic technique by cleansing the port with alcohol or chlorhexidine prior to attaching a syringe and ensuring the extension tubing is clamped when not withdrawing or infusing to prevent development of an air embolism. Additional considerations include ensuring a syringe greater than 10 mL is used to infuse or withdraw to prevent damage to the catheter or the underlying vessel by generating too great of a pressure gradient. Emergency Physicians are advised to utilize pulsatile motion when flushing for similar reasons.¹³ The authors recommend an expert consultation for accessing this device if encountered.

INDICATIONS

PATIENTS REQUIRING INDWELLING CENTRAL VENOUS LINES

Patients of all ages and with a variety of diagnoses may present with an indwelling central venous line. Examples include chronic conditions requiring frequent parenteral analgesia (e.g., sickle cell disease), chronic infections requiring long-term parenteral antibiotics

(e.g., endocarditis, osteomyelitis), and the need for prolonged and frequent access (e.g., chemotherapy, frequent blood sampling, frequent medication infusion, and hyperalimentation). Any patient who requires several weeks of repeated intravenous blood sampling and/or drug administration may be a candidate for an indwelling central venous line.

ACCESS OF INDWELLING CENTRAL VENOUS LINES

Fully or partially implanted central venous access devices may be accessed routinely when intravenous fluids must be administered, medications must be administered, or phlebotomy is required.

CONTRAINDICATIONS

Do not access an indwelling central venous device if peripheral intravenous access can be obtained. The use of bedside ultrasound may facilitate peripheral intravenous access and avoid accessing the indwelling device (Chapter 64). **Always consider the potential risk of damage to the implanted line prior to proceeding with accessing it.** Do not access fully implanted devices through infected overlying skin. Use partially implanted catheters with known or suspected infection cautiously as they may become a source of septic emboli. It is sometimes possible to treat catheter-related infections without requiring removal of the device.^{14,15} **Phenytoin and diazepam cannot be given via silicone indwelling central venous lines.** They can crystallize and permanently obstruct the catheter lumen.¹⁶

Access devices used for hemodialysis only in a true emergency and if no other venous access can be readily obtained. This guideline is intended to prevent loss of the patient's dialysis access due to device damage, infection, or thrombosis. An inability to dialyze the patient in a timely manner may lead to significant morbidity and mortality.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gauze, 4×4 squares
- 10 mL syringes
- 20 gauge needles
- Sterile 0.9% saline
- Heparinized saline flush (e.g., 100 and 1000 U/mL)
- Adhesive tape
- Luer-lock caps
- Blood collection tubes
- Infusion set
- Huber needle, noncoring right angle or straight angle
- Topical anesthetic (e.g., EMLA cream, ethyl chloride spray, or ice)
- Injectable anesthetic without epinephrine (e.g., 1% lidocaine)
- Sterile alcohol prep pads
- Sterile gloves
- Sterile drapes

PATIENT PREPARATION

Discuss the necessary procedure with the patient and/or their representative. Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Consider involving the patient in the decision to perform the procedure. Patients with indwelling lines are usually quite familiar with the care and use of their devices. Patients can often advise the Emergency Physician on the correct procedure, the appropriate flush solution, and any anatomic manipulations necessary to optimize flow through the line (e.g., raising the arms, turning the head). **Sterile technique is required when accessing indwelling central venous catheters.**

Prepare the skin over implanted catheters or the distal portion of partially implanted catheters. Remove any tape from the area. Clean the skin or distal catheter of any blood, debris, or dirt. Apply chlorhexidine solution or povidone iodine and allow it to dry. Drape around the area to delineate a sterile field. Remove any iodine residue with an alcohol pad.

TECHNIQUES

PARTIALLY IMPLANTED CATHETERS

Accessing a partially implanted central venous catheter is simple and similar to accessing a heparin-locked peripheral intravenous catheter.^{10,16} Remove any adhesive tape and gauze wrapped around the distal end of the lumen to be accessed. Fasten the catheter clamp on the desired lumen (**Figure 66-3**). Clean the catheter cap and Luer adapter with povidone iodine or chlorhexidine solution and allow it to dry. The technique for accessing the catheter will vary depending on whether blood sampling with or without a subsequent infusion is required. Both techniques are described below.

BLOOD SAMPLING FROM PARTIALLY IMPLANTED CATHETERS

Blood samples may be withdrawn through the catheter cap using a 20 gauge hypodermic needle attached to a 10 mL syringe if blood

TABLE 66-2 Volumes and Concentrations of Heparin Flushes for Pediatric Indwelling Devices

	Children < 6 months old	Children > 6 months old
Partially implanted device	3 mL heparin (10 U/mL)	5 mL heparin (100 U/mL)
PICC line	3 mL heparin (10 U/mL)	5 mL heparin (100 U/mL)
Fully implanted device	3 mL heparin (10 U/mL)	5 mL heparin (100 U/mL)

is to be sampled without beginning an infusion. **Avoid using syringes smaller than 5 mL as they create a larger pressure gradient upon infusion and risk potential damage to the catheter.**⁴ Insert the needle through the Luer cap. Open the catheter clamp. Withdraw 5 mL of blood from the catheter. Discard the blood sample, needle, and syringe. This blood sample is considered contaminated by the catheter contents (i.e., saline or heparinized saline) and does not represent circulating blood. This step is essential when accessing dialysis catheters as they may contain concentrated heparin (e.g., 1000 U/mL). Gently flush the catheter with 2 to 3 mL of sterile saline if unable to aspirate blood. Refer to Chapter 65 for further troubleshooting instructions if the catheter does not flush easily.

Withdraw the required blood samples using a new needle and syringe inserted through the Luer cap. Carefully transfer the blood samples into collection tubes for the laboratory. The catheter must now be flushed to prevent clot formation. Flush the catheter with the appropriate solution using a 10 mL syringe armed with a 20 gauge needle. Flush the indwelling line with the appropriate volume and concentration of heparin solution to prevent thrombosis (**Table 66-2**). Wipe off the cap with an alcohol pad.

Secure the free end of the catheter. Tape the catheter to the patient's chest wall to prevent accidental traction on the catheter. Evaluate the skin puncture site to ensure the line has not been dislodged. Reapply a dressing over the skin puncture site if necessary.

BLOOD SAMPLING AND INFUSION THROUGH PARTIALLY IMPLANTED CATHETERS

The Luer catheter cap can be removed entirely and the catheter lumen accessed directly with a Luer-hub syringe if an infusion is to be subsequently started. **Ensure that the catheter clamp is securely closed.** Remove the cap from the catheter. Attach a 10 mL syringe to the hub of the catheter. Open the catheter clamp. Withdraw 5 mL of blood into the syringe. Close the catheter clamp. Remove and discard the syringe with the contaminated blood sample. Apply a new syringe, open the catheter clamp, and withdraw the required aliquot of blood. Close the catheter clamp before removing the syringe. Continue this sequence of events until all required blood samples are obtained. **It is imperative to ensure that the catheter is clamped each time the cap or syringe is removed to prevent a potentially life-threatening air embolism.** Securely attach primed intravenous tubing to the hub of the catheter, open the catheter clamp, and begin the infusion.

Clamp the catheter lumen when terminating the infusion or if no infusion is to be started. Remove the intravenous tubing or the syringe from the catheter. Attach a syringe containing the appropriate flush solution, open the catheter clamp, and flush the catheter. Close the catheter clamp. Remove the syringe. Apply a new sterile cap onto the hub of the catheter. **Never use "needle-less" caps as they are a potential source of air emboli.** Upon completion of the infusion, open the catheter clamp to prevent catheter damage from prolonged clamping. Secure the catheter to the patient's chest wall.

FULLY IMPLANTED CATHETERS

A **noncoring Huber-type needle** (Figures 66-6 and 66-7) **must be used to access subcutaneous injection ports to prevent permanent fenestration.** A small-gauge standard hypodermic needle should only be considered for emergent indications if a noncoring needle is not immediately available. Damage to the diaphragm can lead to subcutaneous hemorrhage and necessitate surgical replacement of the implanted device.

Clean and prep the skin overlying the injection port with povidone iodine or chlorhexidine solution and allow it to dry. The application of a topical or injectable anesthetic over the reservoir is optional but often greatly appreciated by the patient. Remove the iodine solution from the skin with an alcohol swab. Flush the Huber needle and extension tubing with normal saline using a 10 mL syringe. Leave the syringe attached. Locate the center of the self-sealing membrane or diaphragm. Stabilize the reservoir with the nondominant hand (Figure 66-6). Slowly and steadily insert the needle through the skin and into the reservoir (Figure 66-6). Stop advancing the needle when it touches the far wall of the device. Gently flush 2 to 3 mL of saline through the needle to ensure proper placement. Refer to Chapter 65 for troubleshooting instructions if the catheter does not flush easily.

Secure the Huber needle in place if the catheter can be flushed easily. Stabilize it with gauze squares and tape. Withdraw 5 to 10 mL of blood. Close the clamp on the extension tubing of the Huber needle (Figure 66-6). Remove and discard the syringe. Attach a new syringe, open the clamp, and withdraw the required blood samples. Clamp the extension tubing and remove the syringe. Attach the primed intravenous tubing if an infusion is to be started and begin the infusion. Clamp the extension tubing if no infusion is desired or when discontinuing an infusion and disconnect the intravenous tubing. Attach a 5 or 10 mL syringe containing heparinized saline (e.g., 100 to 200 U/mL) to the Huber needle extension tubing. Open the clamp and flush the device with 3 to 5 mL of heparinized saline. Flush with saline if a Groshong catheter is attached to the reservoir. Remove the Huber needle from the skin. Control any skin bleeding with direct pressure. Apply a sterile dressing.

An alternative to the Huber needle is the Gripper Safety Needle (Smiths Medical, Dublin, OH). This is a noncoring safety needle mounted in a plastic base (Figure 66-8). The sharp inserter is removed to leave the small blunt cannula in the reservoir. The foam

pad against the skin is convenient for health care personnel and comfortable for the patient. The device comes in numerous sizes and needle gauges.

PEDIATRIC CONSIDERATIONS

The management of pediatric indwelling devices is similar to that in adults with a few exceptions. The catheters, reservoirs, and tubing are often smaller than those used in adults or adolescents. The volumes and concentrations of heparin flushes differ in these smaller catheters (Table 66-2). The external portion of partially implanted devices and PICC lines must be properly secured with a dressing to ensure that the child does not dislodge the device, intentionally or otherwise. Consider expert consultation in the unlikely event that a PCVC is encountered in the Emergency Department.

OTHER INDWELLING DEVICES

Subcutaneous reservoirs may be attached to peripheral veins and body cavities for the same indications (Figure 66-2). These devices may have to be accessed in the Emergency Department. The method for access is the same as described above.

ASSESSMENT

Assessment of line function after accessing a central venous access device will not occur until the next access attempt. Troubleshooting nonfunctioning indwelling central venous lines is discussed in Chapter 65.

AFTERCARE

Secure the partially implanted catheter to the skin with tape to minimize the risk of dislodgement. Give the patient a written record of how the access device was used and flushed in the Emergency Department to convey to their Primary Care Physician should problems with the line become evident later. Document this also in the medical record. Patients must regularly assess their indwelling access sites for signs of infection (e.g., erythema, pain, purulent discharge, or serous discharge). Instruct the patient to immediately contact their Primary Care Provider or return to the Emergency Department if they develop a fever or other signs concerning for infection.

TABLE 66-3 Recommendations to Prevent Infections

An assistant watches procedure and stops it if aseptic technique is breached
 Change administration sets per hospital policy
 Change dressing if dirty, loose, or wet
 Cover with transparent dressings
 Daily chlorhexidine baths for the patient
 Disinfect using mechanical friction
 Educate the patient on proper care
 Maintain aseptic technique
 Minimize access
 Only access devices with proper equipment
 Only access if necessary
 Only insert if necessary
 Remove for complications
 Remove for signs of local skin infection
 Remove if no longer needed
 Use an insertion checklist
 Use approved skin disinfectant solutions
 Use chlorhexidine-impregnated dressings
 Wash hands before accessing, dressing, inserting
 Wash hands before touching the skin access site

COMPLICATIONS

Two of the most important considerations while accessing indwelling lines are to reduce the risk of thrombus formation and infection. Strict adherence to the procedures described above will minimize the chances of these problems. There are many recommendations to prevent an infection (Table 66-3).¹ Complications associated with the presence of the catheter include catheter-related infections, pulmonary embolism, right atrial erosion with pericardial tamponade (rare with implanted lines), and right atrial thromboses.^{10,15,17-19} Fully implanted catheters may become disconnected from the subcutaneous reservoir or may leak into the subcutaneous tissue due to diaphragm failure. Any hematoma formation near the reservoir must be assessed promptly to prevent major hemorrhage.

Suspect an air embolism immediately if the patient becomes confused, hypotensive, and/or tachycardic while accessing the central venous access device. This complication is preventable by ensuring that the catheter tubing is clamped whenever the end of the tubing is being accessed or uncapped. Never attach needle-less tubing to the device. Immediately place the patient in the Trendelenburg position with the left lateral decubitus position if air embolism is suspected. This positioning will hopefully cause air emboli to collect in the apex of the right ventricle instead of entering the pulmonary artery.

Repair kits are available to repair damaged partially implanted catheters. These kits may obviate the need for device removal and replacement if successful. Apply a smooth catheter clamp proximal to the damaged area if the external tubing of the partially implanted catheter is damaged. Arrange to have the device repaired as soon as possible. Instructions for the use of these kits are beyond the scope of this chapter.

SUMMARY

The Emergency Physician will encounter many patients with indwelling central venous catheters. Careful adherence to sterile technique, proper blood sampling technique, and proper infusion techniques will allow access for fluid administration, medication administration, and phlebotomy while preserving the indwelling line for future use and minimizing risk to the patient.

Pulmonary Artery (Swan-Ganz) Catheterization

J. Elizabeth Neuman and Jessica Mann

INTRODUCTION

The concept of invasive hemodynamic monitoring was first pioneered in the mid-1800s. After that time, various devices and techniques evolved until Swan and Ganz developed the balloon-tipped pulmonary artery catheter (PAC) in 1970.¹⁻³ The "Swan-Ganz catheter" has been used almost exclusively in the intensive

care setting ever since, with an estimated 1 million PACs placed annually at a cost of approximately 2 billion dollars.^{4,5} The use of the PAC has allowed clinicians to measure right atrial, pulmonary artery, and pulmonary capillary wedge pressures at the bedside.⁶ Although advanced hemodynamic monitoring would seem intuitively to help clinicians in the management of unstable patients, the PAC has not been found to improve survival, and its use has declined significantly over the past 20 years.⁷ While the utility of the PAC has become less clear, particularly with advances in less invasive monitoring techniques, it is still used in complex cases.⁸ This chapter focuses on the actual technique of placement of the PAC and is predicated on the ability of the Emergency Physician (EP) to gain central venous access (Chapters 63 and 64).

ANATOMY AND PATHOPHYSIOLOGY

Central access is generally obtained via the right internal jugular or left subclavian vein. Using either of these access points allows the easiest passage of the PAC into the right atrium (RA) from the superior vena cava (SVC) (**Figure 67-1**). The left internal jugular, right subclavian, or femoral veins may be used but are more technically challenging. Use of the flexible balloon-tipped catheter allows it to “float” with the blood flow through the tricuspid valve into the right ventricle (RV). From there, the catheter travels through the RV outflow tract, through the pulmonic valve, and into the pulmonary artery (PA). Direct measurements of central venous pressure (CVP), right ventricular pressure, pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP), and mixed venous saturation can be made.⁹ The ability to measure the central venous oxygen saturation (ScvO₂) provides of the most crucial pieces of information to the EP. This represents the balance of oxygen delivery versus consumption and is critically important in the management of patients in shock.

The balloon of the PAC is inflated and “wedges” into a branch of the PA to occlude blood flow into that segment (**Figure 67-2**). The catheter, therefore, measures the downstream pressure in the vessel. This PAWP has been shown to correlate closely with left atrial pressure (LAP).⁷ During diastole, the mitral valve is open and the LAP

FIGURE 67-1. Cardiac anatomy as it pertains to PAC insertion. The PAC enters the right atrium from the superior vena cava, crosses the tricuspid valve into the right ventricle, and then crosses the pulmonic valve into the pulmonary artery. The catheter tip lies in a branch of the right pulmonary artery.

FIGURE 67-2. Diagram of the principle underlying pulmonary capillary wedge pressure. Balloon inflation blocks transmission of the forward pulmonary artery pressure to the tip of the catheter. The catheter tip therefore measures the downstream pressure of the pulmonary circulation. Because the pulmonary circulation has no valves, the pressure measured at the catheter tip is equal to the pressure in the left ventricle when the mitral valve is open (diastole).

is equal to left ventricular end-diastolic pressure (LVEDP). Knowing the LVEDP is important because it provides the best estimate of preload, allows for the assessment of left ventricular filling, and can theoretically help guide the resuscitation.⁹

The PAC may also be used to measure the cardiac output using the thermodilution method. The tip of the PAC has a temperature-sensitive probe. When a given volume of cold saline is injected into the right atrial port of the PAC, it cools the temperature of the blood flowing past the catheter tip. If the cardiac output is high, the cold saline is mixed with and carried along by a larger flow of blood so that the temperature change detected at the PAC tip is smaller and dissipates faster. If cardiac output is low, the cold saline mixes with a smaller volume of blood, and the temperature change is more apparent and slower to dissipate.

INDICATIONS

Classically, the PAC has been used in the critical care setting to aid in the management of patients with sepsis, left ventricular dysfunction, myocardial ischemia, and multiple other causes of hemodynamic instability. Measuring cardiac output (CO) and ScvO₂ helps guide therapy, but there are no data to suggest that the use of the PAC improves outcomes.¹⁰⁻¹⁴ A 2013 Cochrane review found 13 randomized controlled trials totaling 5686 patients.¹⁵ It found no difference in death, intensive care unit length of stay, or hospital length of stay between patients in whom the PAC was and was not used.¹⁵ As with any intervention, the EP must carefully assess the potential benefits and risks in making the decision to place a PAC. **Table 67-1** lists the most widely accepted indications for the use of a PAC.

CONTRAINDICATIONS

Contraindications to actual placement of a PAC include refusal of consent, infection at the insertion site, and the presence of a right ventricular assist device. Placement of the PAC is contraindicated

TABLE 67-1 Common Clinical Indications for Pulmonary Artery Catheter Placement in Medical and Surgical Patients**Cardiac**

- A. Complicated myocardial infarction
 - i. Management of refractory hypotension or left ventricular failure
 - ii. In presence of hemodynamic deterioration due to a mechanical complication, to differentiate mitral regurgitation from acute ventricular septal defect
- B. Other cardiac conditions
 - i. Diagnose/manage cardiac tamponade
 - ii. Distinguish cardiogenic from noncardiogenic pulmonary edema
 - iii. Management of severe cardiomyopathy
 - iv. Diagnose/manage severe pulmonary hypertension

Medical/Surgical

In the setting of sepsis, trauma, burns, multiple organ failure, pulmonary embolus, or drug overdose.

If any of the following is found to be unresponsive to conventional medical management:

- A. Hypotension
- B. Low urine output
- C. Hypoperfusion (evidenced by cool skin, mental obtundation, lactic acidosis)
- D. Severe hypoxemia requiring high levels of positive end-expiratory pressure (> 10 cm)

Preoperative

- A. High-risk cardiac surgery (e.g., coronary artery bypass graft in elderly patients, multiple valve replacement, ventricular aneurysm resection)
- B. Complicated vascular surgery (dissecting aneurysm, resection of thoracic or abdominal aneurysm)
- C. Other surgical patients with multiple risk factors
 - i. Myocardial infarction within 6 months
 - ii. Poor left ventricular function
 - iii. Elevated Goldman or American Society of Anesthesiologists score

if less invasive monitoring options (e.g., echocardiography) will provide the EP with the information needed. Competence of the EP to place, use, and interpret the data provided by the PAC and the availability of required equipment are prerequisites. Laboratory evaluation should be undertaken prior to the procedure because electrolyte abnormalities and severe acid-base disturbances can predispose to dysrhythmias. Risk versus benefit must be weighed carefully in cases of coagulopathy, bleeding diathesis, or known right heart thrombus. Routine placement of PAC prior to low-risk operative procedures is not recommended per the latest American Society of Anesthesiologists task force on PA catheterization.¹⁶

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask and cap
- Saline or dextrose solution with or without heparin (1 to 2 U/mL)
- Pressure bag with manometer
- Pressure tubing
- Pressure transducer for distal port (CVP port optional)
- Stopcocks and occlusive caps for each port of the PAC
- Fluid infusion tubing for sheath sideport and for PAC ports
- PAC
- Balloon inflation syringe
- Catheter sleeve
- Sterile dressing for site
- Electrocardiogram (ECG) and pressure monitor

Insertion of the PAC requires placement of a percutaneous introducer sheath, typically 8.5 French in size (Chapters 63 and 64).¹⁷

**FIGURE 67-3.** The pulmonary artery catheter.

Please refer to Chapter 63 for a detailed review of introducer sheath placement. The PAC is placed in a sterile sleeve that allows for aseptic manipulation of the catheter.¹⁴ The PAC itself (**Figure 67-3**) is a flexible, balloon-tipped catheter that typically is able to accommodate a cardiac pacing wire. The catheter is a triple-lumen catheter with a proximal port/lumen at about 30 cm from the tip, a thermistor used to calculate CO, a balloon just proximal to the tip, and a distal lumen that opens at the end of the catheter. The catheter is marked in 5 cm increments to guide insertion. Each catheter comes with a 3 mL syringe that is used to inflate the balloon.

PATIENT PREPARATION

Preparation plays a very important role in any procedure. Routine laboratory studies are advisable prior to PAC insertion in nonemergent circumstances. Hematologic abnormalities (e.g., severe anemia, thrombocytopenia, and coagulation system deficiencies) can increase the risk or adverse consequences of bleeding. Electrolyte derangements (e.g., hyperkalemia, hypokalemia, and hypomagnesemia) that may predispose to arrhythmias should be identified and corrected when possible.

Explain to the patient and/or their representative the risks, benefits, and complications of the procedure. Obtain informed consent for the procedure if possible. The use of mild sedation may be advantageous in some patients. Sedation may be required in the appropriate clinical setting if the patient cannot lie still for the procedure. Place the patient supine if possible. Continuous ECG monitoring is essential. Pulse oximetry should be routinely monitored. Arterial pressure monitoring is often desirable in patients receiving a PAC. Apply supplemental oxygen. Equipment and personnel

necessary for assisting with the PAC insertion procedure and for managing potential complications should be immediately available. This should include equipment for emergency airway management and emergency cardiac pacing.

The choice of which central venous access site to use for PAC insertion must be individualized. The preferred sites are the right internal jugular vein or the left subclavian vein. The PAC tends to float into the desired position more easily from these two sites. The left internal jugular vein and the right subclavian vein are acceptable alternatives. The femoral vein may also be used. The femoral approach may be quite difficult without fluoroscopic guidance of the catheter. The external jugular veins, basilic veins, and axillary veins are additional alternatives that carry the same difficulty.

It is essential that strict sterile technique be maintained throughout the insertion procedure. The EP and their assistant should be wearing sterile gloves, a sterile gown, a face mask, and a cap. A large sterile field is necessary, as is close attention to the long PAC, which can easily become contaminated. It is also very important to take all necessary precautions with syringe needles, scalpel blades, and suture needles to prevent a needle-stick injury.

Insert a percutaneous introducer sheath into the central venous system (Chapters 63 and 64). If the patient already has a single-lumen or multilumen central venous catheter inserted, it may be exchanged for an introducer sheath. Remove any bandages and dressings on the catheter and skin access site. Thoroughly prep the catheter, skin access site, and surrounding skin with povidone iodine or chlorhexidine solution and allow it to dry. Drape a sterile field. Discontinue any infusions through the catheter. Open an introducer sheath kit. Cut any sutures securing the catheter to the skin. Insert a guidewire through the hub of the distal port and into the central venous circulation. Withdraw the catheter over the guidewire. Insert and secure the percutaneous sheath over the guidewire.

Take the time to reassure the awake patient and explain what will be happening. Patients in general will be draped and their faces covered, which can be frightening. Verbal reassurance should be frequent, and anxiolysis may be necessary to ensure that they stay still.

TECHNIQUE

Set up a bedside sterile table and open the PAC kit. Remove the protective sleeve. It allows later repositioning of the PAC while maintaining sterility. Place the sleeve over the catheter and slide it far back (> 60 cm) from the catheter tip. Attach the balloon inflation syringe to the PAC. Inflate the balloon with 1.5 mL of air to confirm the integrity of the balloon. It is a good idea to inflate the balloon in a full bowl of sterile saline. Observe for air bubbles to ensure that there are no leaks or gross eccentricities. Check the balloon to ensure it inflates properly and symmetrically and deflates adequately.¹⁸ Allow the balloon to deflate passively. **Deflation by aspirating air from the balloon should be avoided as it places undue stress on the balloon and increases the risk of rupture.**

Flush the PAC ports with sterile saline and attach a stopcock to each port. Attach the pressure tubing to the distal port. Flush the entire apparatus, including the PAC and the pressure monitoring system, with sterile saline to ensure that no air remains in any part of the system. Have an assistant set up, calibrate, and level the transducer. The transducer must be leveled to ensure pressures are measured against a standard reference level.¹⁸ Hand the proximal end of the PAC to an assistant to attach to the ECG monitor. Finally, shake the tip of the PAC while observing the pressure waveform on the monitor to confirm that the monitoring system is operative.¹⁸

Prior to the insertion, allow the PAC to rest in its natural curvature. Insert the PAC through the diaphragm on the introducer sheath, taking care to orient the natural curve of the catheter toward the RV outflow tract. Continue to advance the PAC until it is inserted 10 to 15 cm and exits the sheath. **This ensures that the balloon is not inflated within the sheath. Stop advancing the PAC.** Inflate 1.5 mL of air into the balloon and lock the pressure release valve. **The PAC should never be advanced through the central venous system with the balloon deflated, as this may provoke ectopy, injure the heart, or injure other vascular structures. Conversely, the PAC should always be withdrawn with the balloon deflated.**

Pay close attention to the distance markings on the PAC and to the pressure waveform on the monitor when advancing the PAC. Typical pressure waveforms are illustrated in **Figure 67-4**. The average distances from the different catheter insertion sites into each chamber of the heart are listed in **Table 67-2**. Advance the PAC

FIGURE 67-4. Typical pressure waveforms recorded by the PAC during insertion.

TABLE 67-2 Average Distances from the Catheter Insertion Site to the Catheter Tip Position*

Catheter insertion site	Right atrium distance (cm)	Right ventricle distance (cm)	Pulmonary artery distance (cm)	Wedge distance (cm)
Subclavian vein	10	20	30–40	40–45
Right internal jugular vein	15	25	35–45	45–50
Left internal jugular vein	20	30	40–50	50–55
Right antecubital vein	45	60	70–80	80–85
Left antecubital vein	50	65	75–85	85–90

*These distances are considered the common estimates for uncomplicated PAC placement in patients with normal-sized hearts. The distances will vary in patients and may be greater, especially in the patient with a dilated right ventricle. Any time there is a gross discrepancy between these distances and the actual observed placement distance, the physician should consider catheter misplacement, catheter looping, or catheter knotting. An immediate portable anteroposterior chest radiograph should be obtained to evaluate the situation.

into the low-pressure right atrium (**Figure 67-4A**). Prior to the insertion, allow the PAC to rest in its natural curvature. Insert the PAC such that its natural curvature follows in the direction of the RV outflow tract. Continue to advance the PAC into the right ventricle, which will be apparent by an abrupt change in the pressure waveform (**Figure 67-4B**). This occurs at approximately 30 cm of insertion. There is a larger amplitude waveform with a sharp upstroke in the higher pressure RV (**Figure 67-4B**). **The PAC may be coiled in the RA or migrated into the inferior vena cava if this waveform is not obtained. Continuing to insert the catheter further can increase the risk of knotting.**¹⁷

Advance the PAC if the classic RV waveform is obtained. At about 40 to 45 cm, the PA is reached, yielding a waveform with a sharp upstroke and downstroke and the classic “dicrotic notch” (**Figure 67-4C**).¹⁷ The PA is occluded by advancing the balloon a few centimeters further, yielding the PAWP. This final waveform will be similar to that observed when the catheter is in the RA (**Figure 67-4D**).¹⁸ Passing the PAC through the right ventricle may produce some ventricular ectopy, which is generally uncomplicated.

Deflate the balloon, and the PAP waveform should again be visualized. **If the PAP waveform does not return and the PAWP waveform persists, withdraw the PAC with the balloon deflated until the PAP waveform is again recognized.** This problem can be encountered when the PAC migrates far enough that the catheter itself occludes the PA without the balloon inflated. **Leaving the PAC wedged in this position can cause pulmonary infarction. The PAC balloon should never be left inflated.** Correct PCW positioning can also be confirmed by withdrawing a blood sample and checking a blood gas. A sample from the wedge position should have an oxygen saturation of > 94%.¹⁷

Whenever it is unclear where the tip of the PAC is located, deflate the balloon and withdraw the PAC to a spot where the waveform is recognizable. Take notice of the distance marking. Inflate the balloon and advance the PAC until the desired tracing is obtained.

Difficulties in passing the PAC into the PA may occur in patients with pulmonary hypertension, significant tricuspid regurgitation, or markedly dilated right heart chambers. Instruct the patient to inspire slowly and deeply to increase venous return to the right heart. This may allow the PAC to be advanced successfully. Tilting the patient’s head upward and repositioning the patient on their left side may also be helpful. Fluoroscopic guidance may be necessary if repeated attempts are unsuccessful.

Pull up the protective sleeve over the catheter and secure it to the introducer sheath. It is important not to advance the PAC itself

FIGURE 67-5. The PAC in position as viewed on the anteroposterior chest radiograph. (Image courtesy of Dr. Alex Yartsev.)

during this manipulation. Begin any infusions through the PAC. The PAC should be secured to the skin with sutures. Apply a sterile dressing. Care of the catheter and skin site are covered in Chapters 63 and 64. Obtain a chest radiograph to confirm placement and evaluate for a pneumothorax. The tip of the PAC should be at or below the level of the left atrium, generally no more than 2 cm from the hilum and 3 to 5 cm from the midline (**Figure 67-5**). This position corresponds to West Zone 3 of the lung, which is the most dependent portion in which the PAP and PAWP exceed alveolar pressure.¹⁹

DATA INTERPRETATION

A detailed discussion of PAC data interpretation cannot be undertaken here. However, anyone who places or uses PACs in the management of critically ill patients should be familiar with the standard information provided by the PAC. To obtain and interpret data from the PAC, the monitoring system must be calibrated and zeroed and the transducer leveled. **The PAWP will not be accurate if these steps are not taken.** Some studies have cited that only 30% to 55% of physicians and nurses can correctly identify the PAWP.^{20–23}

The data generated by the PAC can be categorized as that which is directly observed, obtained, or extrapolated.¹⁷ The PAC allows real-time continuous display of heart rate (HR), mean arterial pressure (MAP), CVP, right atrial pressure (RAP), and PAP (**Table 67-3**). PAWP can be obtained by inflating the balloon. Mixed venous oxygen saturation (SvO₂) can be obtained by taking a PA blood sample, and CO can be obtained using thermodilution. These data, including normal values, are listed in **Table 67-3**. The next set of data comprises the variables that are mathematically derived from the measured data (**Tables 67-4 and 67-5**). These provide information crucial to understanding cardiac and pulmonary physiology and pathology.

TABLE 67-3 Variables Obtained from the Pulmonary Artery Catheter Through Direct Measurement

Variable	Normal values	Main utility	Comments
Cardiac output (CO)	4–6 L/min	Diagnosis of shock (high output versus low output); titration of vasoactive medications	Measurement is prone to error; should be indexed to patient's size
Pulmonary capillary wedge pressure (PCWP)	5–15 mmHg	Volume status, diuresis, fluid challenges	Often overinterpreted; must be used with other values
Right atrial pressure (RAP)	0–10 mmHg	Status of right ventricle	Less useful than PCWP
Pulmonary artery pressure (PAP)	15–25 mmHg systolic; 8–15 mmHg diastolic	Status of right ventricle and pulmonary circuit	Pulmonary artery diastolic can be substituted for PCWP in most patients
Mixed venous oxygen saturation (SvO ₂)	70–80%	Evaluation of oxygen delivery; pulmonary shunt fraction	Best obtained by blood gas from distal pulmonary artery

Today, this information is routinely available on an instantaneous basis as part of computer software packages that accompany the monitoring equipment. PAC users should become familiar with the information from the PAC and its application in different clinical situations. The reader is advised to consult a current textbook of cardiology or critical care medicine for a more detailed description of the hemodynamic data provided by the PAC.

COMPLICATIONS

Complications related to the use of PAC are related to three general areas: obtaining central access (Chapters 63 and 64), the catheterization process itself, and those related to the indwelling PAC (Table 67-6). Obtaining central access can result in arterial puncture, pneumothorax, hemothorax, bleeding, and potentially cardiac perforation.¹ The complications directly related to the PAC may be divided into those that are associated with catheter insertion and those associated with maintenance (Table 67-6). Both sets of complications can be further divided into those problems where there has been systematic study and the incidence of complications has been published and those that have been observed and published as case reports but the actual incidence of which is unknown.

Problems with tracing quality may occur due to problems involving the catheter itself or other parts of the system. Catheter problems include positioning too distal or not distal enough, balloon rupture, or clot formation at the tip. Problems elsewhere in the system include air in the lines, loose connections, failure of the transducer, failure of the wires, or failure of the monitor. The system should be

TABLE 67-5 Formulas for the Derivation of Variables

SVR = (mean arterial pressure – mean arterial pressure) × 80 cardiac output
PVR = (mean pulmonary artery pressure – pulmonary capillary wedge pressure) × 80 cardiac output
LVSWI = SV × (mean arterial pressure – pulmonary capillary wedge pressure) × 0.0136 body surface area
RVSWI = SV × (mean arterial pressure – right atrial pressure) × 0.0136 body surface area
DO ₂ = [(cardiac output × hemoglobin) × (13.4) × (% O ₂ saturation)] + (PO ₂ × 0.0031)
VO ₂ = (cardiac output × hemoglobin) × (13.4) × (SaO ₂ – SvO ₂)
Q _s /Q _t = (pulmonary capillary O ₂ content – CaO ₂) ÷ (pulmonary capillary O ₂ content – CvO ₂)

CaO₂, arterial oxygen content; CvO₂, mixed venous oxygen content; PO₂, partial pressure of oxygen; SaO₂, arterial oxygen saturation; SV, stroke volume. Other terms are defined in Tables 67-3 and 67-4.

zeroed and calibrated again to confirm the accuracy of the pressure values if abnormally high or low values are obtained. Sometimes it is just not possible to obtain a good wedge tracing despite repeated attempts. In such cases, the pulmonary diastolic pressure may be used as a surrogate for the wedge.

A right bundle branch block may occur in 5% due to impact of the PAC with the right side of the septum during insertion. This is usually transient. Even if it persists for hours, it is well tolerated in most patients. **However, the superimposition of a right bundle branch block in the presence of a preexisting left bundle branch block leaves the patient with a complete heart block. This complication can result in severe bradycardia and hemodynamic embarrassment. It is important to be prepared to institute temporary transcutaneous or transvenous pacing when placing a PAC in patients with a left bundle branch block.**²⁴

Arrhythmias during insertion, most commonly premature ventricular beats, are usually due to irritation of the right ventricle. This is especially true of the outflow tract. Premature ventricular contractions are usually well tolerated unless sustained ventricular tachycardia or ventricular fibrillation occurs. Slight withdrawal and redirection of the PAC are usually adequate. Arrhythmias after insertion may be due to catheter loops in the right heart, which will be apparent on the chest radiograph and can be corrected by careful withdrawal of the PAC until the loop is removed. Arrhythmias may also occur if the PAC tip slips back into the right ventricle. In this case, the pressure tracing will show a typical RV waveform. Readvancement of the PAC into the PA should eliminate the arrhythmias.

Other potentially serious but rare complications include injuries to the great vessels, trachea, lymphatic duct, vagus nerve, or phrenic nerve as well as a pneumothorax, hemothorax, hemomediastinum, misplacement, and cardiac perforation.^{25,26} On occasion, the PAC can become knotted intravascularly or within the heart during placement. This requires an Interventional Radiologist to unknot it or a Surgeon to remove the PAC if this fails.¹

The most serious complications related to insertion or maintenance of the PAC are PA rupture, PA infarction, and catheter infection. PA rupture can occur at the time of placement or later secondary

TABLE 67-4 Derived Variables Obtained from the Pulmonary Artery Catheter

Variable	Normal values	Main utility	Comments
Systemic vascular resistance (SVR)	800–1600 dynes/sec/cm ⁻⁵	Shock states, vasodilator versus vasopressor therapy (afterload)	Unclear whether value should be indexed to patient's size
Pulmonary vascular resistance (PVR)	20–200 dynes/sec/cm ⁻⁵	Pulmonary hypertension; acute and chronic lung disease	Unclear whether value should be indexed to patient's size
Left ventricular stroke work index (LVSWI)	56 ± 6 gm-m/m ²	Left ventricular performance	Clinical utility uncertain
Right ventricular stroke work index (RVSWI)	8.8 ± 0.9 gm-m/m ²	Right ventricular performance	Clinical utility uncertain
Oxygen delivery (DO ₂)	900–1100 mL/min	Shock states, anemia, low cardiac output	Often amenable to therapy, but controversial
Oxygen consumption (VO ₂)	200–250 mL/min	Sepsis, burns, trauma, ventilator patients	Affected by many variables; use is controversial
Pulmonary shunt fraction (Q _s /Q _t)	3–5%	Acute and chronic lung disease	Underused in the evaluation of pulmonary disease

TABLE 67-6 Recognized Complications of Pulmonary Artery Catheterization**Related to catheter insertion (published incidence)**

Air embolism (0.1%)
 Complete heart block (0–2.6%)
 Hematoma (0–3%)
 Inability to place catheter with multiple attempts (1.7%)
 Injury to great vessels (0.1–13%)
 Pneumothorax (0.1–1.5%)
 Ventricular arrhythmias (20–50%)
 Ventricular arrhythmias requiring treatment (0–3%)

Related to catheter insertion (reported, but incidence not published)

Cardiac perforation
 Catheter knotting (requiring surgical removal)
 Guidewire embolism
 Hemomediastinum
 Hemothorax
 Injury to phrenic or vagus nerve
 Injury to trachea
 Lymphatic duct perforation

Related to long-term maintenance (published incidence)

Catheter infection (1–5%)
 Pulmonary artery rupture (0–0.5%)
 Pulmonary infarction (0–0.5%)

Related to long-term maintenance (reported, but incidence not published)

Catheter shearing with embolization
 Misreading or misunderstanding of data provided by catheter

to migration of the catheter, with a mortality ranging from 30% to 70%.²⁷ PA rupture is usually the result of the catheter becoming overwedged and/or the balloon overinflated.²⁷ Pulmonary infarction has been seen primarily in patients with mitral regurgitation or pulmonary hypertension and may be avoided if the duration of balloon inflation is kept to a minimum. Catheter infection occurs in 1% to 5% of PAC placements and can be minimized by strict sterile maintenance of the PAC as well as continually reevaluating the need for the PAC and keeping the placement time as short as possible.²⁸ Equipment malfunction or failure can also occur. The presence of the indwelling catheter for prolonged periods of time (> 48 hours) increases risk of PA rupture, deep venous thrombosis, pulmonary infarction, and infection.²⁸ The majority of PACs should be used for 72 hours or less.

SUMMARY

At the time of its introduction four decades ago, the PAC was initially embraced by EPs and Critical Care Physicians for its ability to provide real-time information regarding variables such as CVP and pulmonary capillary wedge pressure at the bedside, and PAC use became common practice. However, over the past 15 years, this has come into significant question. At this point, the utility of PAC is unclear. The PAC has not led to improved outcomes, decreased mortality, or decreased intensive care unit length of stay. Thus, its use as common practice cannot be supported. However, there are still many clinical situations for which the use of a PAC may benefit the EP to make crucial decisions. The PAC is a tool in the armamentarium of any clinician taking care of critically ill patients. Therefore, it is important to be well versed in the information that it provides and its application in the clinical context of the disease state that EPs are managing.

Noninvasive and Minimally Invasive Cardiac Output Monitoring

Caleb Canders, Daniel W. Weingrow, and Alan Chiem

INTRODUCTION

More than 1,000,000 cases of shock present to the Emergency Department per year. Many critically ill patients remain in Emergency Departments for extended periods of time. Delays in diagnosis and/or therapy may increase morbidity and mortality.¹ The underlying physiologic abnormality for all types of shock remains inadequate oxygen delivery. The main contributors to oxygen delivery are cardiac output (CO) and oxygen content. Early aggressive management of patients with shock leads to improved outcomes.²

The goals of CO monitoring in shock are to aid in the diagnosis of undifferentiated shock, to accurately measure the patient's hemodynamics, to treat patients more precisely, and to improve patient outcomes. CO and volume status have traditionally been measured by physical examination and invasive monitors (e.g., pulmonary artery catheter and central venous pressure monitoring).³ Noninvasive CO monitoring aims to give the Emergency Physician accurate dynamic monitoring information to guide clinical decision making to optimize preload, administer fluid resuscitation, and administer vasopressors.

CO determination has conventionally been obtained by thermodilution or dye dilution measurements that are invasive and associated with potential risks. Pulmonary artery (PA) catheters (Chapter 67) are considered the reference standard for hemodynamic assessment. PA catheters have complication rates of up to 7%.⁴⁻⁶ Complications of PA catheters include sepsis, arrhythmias, valvar damage, cardiac tamponade, intermittent CO determinations, expense, and restricted use to monitored sites within a hospital (i.e., Emergency Department, Intensive Care Unit, or Operating Room).

Noninvasive devices that measure CO are being used more often and show agreement with the reference standard thermodilution technique. An ideal noninvasive CO monitor should be accurate, reliable, continuous, and compatible with adult and pediatric patients. No single device fits all the criteria despite considerable advancements in CO monitoring. The commercially available modalities for noninvasive CO monitoring fall into three categories: ultrasound (US)-based technology, pulse contour analysis, and thoracic electrical bioimpedance. This chapter reviews the available technology and its applications and limitations.

ULTRASOUND-BASED TECHNOLOGY

Christian Doppler identified that the velocity of a moving object is proportional to the shift in reflected frequency of an optic wave of known frequency. This principle has been adapted to sound waves and is now the basis for Doppler devices that can continuously measure the velocity of blood flow and related hemodynamic variables. The first use of Doppler to measure the velocity of red blood cells in humans or animals occurred in 1969.⁵ Commercial devices are available that measure blood velocity in the thoracic aorta via a transcutaneous or transesophageal approach. The USCOM 1A (Ultrasonic CO Monitor, Uscom Ltd., Sydney, Australia) and the Oesophageal Doppler Monitor (ODM; CardioQ, Deltex Medical Inc., Greenville, SC) display continuous hemodynamic data (e.g., CO, peak velocity, and corrected flow time) and the characteristic flow-velocity waveform (Figures 68-1 and 68-2). **Point-of-care US can be used to assess CO and fluid responsiveness.**

POINT-OF-CARE ULTRASOUND

ANATOMY AND PATHOPHYSIOLOGY

CO is the product of heart rate (HR) and stroke volume (SV) (i.e., $CO = HR \times SV$). The left ventricular outflow tract (LVOT) lies proximal to the ascending aorta. Velocity in the LVOT changes with factors that influence stroke volume (e.g., respiratory variation, fluid administration, or passive leg raise [PLR]). Any changes in LVOT velocities will be directly linked to changes in CO or SV.

Fluid responsiveness is an important concept in the management of septic patients. Fluid responsiveness has been traditionally defined as an increase in CO or SV by more than 10% after an isotonic fluid bolus of 500 mL.⁶ PLR is a maneuver that results in an intrathoracic autotransfusion of blood from the lower extremities that is hemodynamically similar to a 300 to 500 mL intravenous fluid bolus. PLR has been well validated combined with a CO monitor

FIGURE 68-2. The CardioQ ODM monitor. (Photo courtesy of Deltex Medical Inc.)

and is a good predictor of response to subsequent volume challenges in studies involving mechanically ventilated and spontaneously breathing patients.⁷⁻⁹ A pre-to-post PLR CO change of $\geq 15\%$ or SV change $\geq 13\%$ has been shown to predict fluid responsiveness.¹⁰⁻¹³

SV can be calculated by multiplying the sum of velocities in one systolic ejection cycle (i.e., known as the velocity-time integral [VTI]) by the cross-sectional area (CSA) of the aortic valve or the LVOT. The Emergency Physician can strictly focus on the changes in VTI given that CSA does not change. A change in VTI and the maximal velocity (V_{\max}) with respiratory variation, fluid administration, or PLR can be used to assess fluid responsiveness. LVOT-derived stroke volume variation $\geq 13\%$ with PLR and respiratory variation in septic shock patients in the Intensive Care Unit has been shown to be highly predictive of fluid responsiveness.¹⁴⁻¹⁶

Figure 68-3 shows the measurement of LVOT Δ VTI and the change in (Δ) V_{\max} using an apical five-chamber window. Each negatively deflected peak represents the sum of velocities of blood (or VTI) traveling through the LVOT during systole. The V_{\max} is the fastest blood velocity recorded in the peak. The changes in V_{\max} or VTI are due to respiratory variation or PLR. A Δ VTI $> 20\%$ or $\Delta V_{\max} \geq 13\%$ predicts fluid responsiveness.

Changes to carotid blood flow (CBF) have been shown to be associated with fluid responsiveness when compared to a

FIGURE 68-3. Measurement of LVOT Δ VTI and ΔV_{\max} using an apical five-chamber window. See text for details.

FIGURE 68-4. Changes in CBF with PLR to predict fluid responsiveness. See text for details.

combined PLR and bioreactance method. A Δ CBF $\geq 20\%$ with PLR predicts fluid responsiveness with a high sensitivity and specificity.¹³ CBF measurement has the advantage that many Emergency Physicians are already able to identify the carotid artery due to experience using US for internal jugular central venous catheterization. Carotid flow time (CFT) is derived from carotid Doppler tracings and has been proposed as a method to assess for fluid responsiveness. CFT reflects the duration of systole in the cardiac cycle. Animal models of hemorrhage show that the CFT decreases when intravascular volume is depleted and CFT increases after fluid administration.¹⁷

Figure 68-4 shows the assessment changes in CBF with PLR to predict fluid responsiveness. The common carotid artery is identified in the long axis, and a pulsed wave Doppler (PWD) tracing is obtained. The diameter of the vessel is measured. The interval (**Figure 68-4, inset**) represents one cardiac cycle. The left marker indicates the beginning of systole. A diastolic notch (*arrow*) indicates the beginning of diastole. The right marker indicates the end of diastole. The tracing of the velocity between this interval is referred to as the time-average peak (TAP), which is conceptually similar to the VTI. CBF is obtained by multiplying the TAP with the diameter, making it a surrogate estimate for SV.

Figure 68-5 shows the assessment of corrected CFT. The carotid artery is imaged in its long axis, and a PWD tracing is obtained. The systole time and the entire cardiac cycle (i.e., cycle time) are

FIGURE 68-5. Assessing the corrected CFT. See text for details. CT, cycle time; ST, systolic time.

measured. A CFT is calculated by dividing systole time with the square root of the cycle time. A $\Delta\text{CFT} \geq 20\%$ is suggested to predict fluid responsiveness.

INDICATIONS

Point-of-care US is indicated in patients in whom estimations of the CO and fluid responsiveness are needed and noninvasive methods are desired that can be readily repeated to evaluate response to treatment.

CONTRAINDICATIONS

A major disadvantage to point-of-care US, especially when performing advanced Doppler echocardiography, is the skill required of the Emergency Physician. LVOT VTI and V_{max} measurements require more advanced skill in acquiring images and performing calculations. An adequate apical five-chamber view may not be obtainable in some cases. There can be 20% to 30% variation from actual flow if the angle of the US beam (i.e., the insonation angle) is $> 30^\circ$ off flow.¹⁷ Despite these issues with image acquisition, point-of-care US has good agreement between expert sonographers and Emergency Physicians, with optimal VTI measurements obtained nearly 80% of the time by Emergency Physicians.¹⁸ The LVOT VTI may not be accurate when the cardiac rhythm is irregular because of beat-to-beat variation in diastolic filling.

EQUIPMENT

The only equipment required is a portable point-of-care US machine and transducer that can acquire two-dimensional images and Doppler measurements. A phased array probe is ideal for LVOT measurements. A linear probe is ideal for carotid artery measurements. Cardiac calculations software must be installed on the machine for LVOT measurement.

TECHNIQUE

The LVOT diameter is measured in the two-dimensional mode using the parasternal long axis. Measure the diameter 0.5 cm proximal to the aortic valve leaflet insertions in systole (i.e., when the semilunar valve leaflets are open). Most US machines will calculate the cross-sectional area of the LVOT based on the diameter. Obtain an apical three- or five-chamber view. Place the PWD gate in the LVOT as close to the aortic valve as possible without including it. The PWD gate should be 2 to 4 mm. Acquire the PWD waveform. Choose LVOT VTI from the calculation menu, and manually trace the PWD waveform. Some US machines can calculate this automatically. The US machine will calculate the area under the curve and represent it as a VTI. Perform the VTI measurement three times, and average the results to reduce sampling bias. Calculate the SV by multiplying the LVOT VTI and the LVOT CSA. Calculate the CO by multiplying the SV and HR.

For carotid Doppler flow measurements, visualize the carotid artery in its long axis using a linear probe. Measure the diameter of the carotid artery within 0.5 cm of the common carotid bulb during systole. Place a PWD gate at the same location in the middle of the artery to determine the VTI. The angle of insonation should be 45° to 60° . Calculate the SV by multiplying the LVOT VTI and the LVOT CSA. Calculate the CO by multiplying the SV and HR.

SUMMARY

Point-of-care US performed at the bedside can be used to determine CO. CSAs and VTIs can be measured at the LVOT or major

arteries. Point-of-care US is noninvasive, readily available, and relatively inexpensive compared to other cardiac monitoring devices. The major drawback is that image acquisition and interpretation are operator dependent. Point-of-care US has the potential to be an effective adjunct in assessing fluid responsiveness and guiding resuscitation in critically ill patients.

ESOPHAGEAL DOPPLER MONITORING

ANATOMY AND PATHOPHYSIOLOGY

SV can be determined by multiplying the spatial average blood velocity within the aorta during systole (V), ejection time (ET), and the CSA of the aorta (i.e., $\text{SV} = V \times \text{ET} \times \text{CSA}$). The descending aorta CSA is related to the height, age, and weight of the patient. Determination of CO using this formula is an approximation based on patient variables rather than a precise measurement.

The device displays the peak velocity and flow time (FT) once the esophageal Doppler monitor (EDM) is inserted and the flow-velocity waveform is obtained. The peak velocity is the apex of the waveform, and the FT is the length of the waveform base (**Figure 68-6**).¹⁹⁻²¹ The FT is HR dependent. The FT must be corrected (FTc) given that most hemodynamic interventions will affect HR.

The normal range for peak velocity is age dependent: 90 to 120 cm/sec for a 20-year-old, 70 to 100 cm/sec for a 50-year-old, and 50 to 80 cm/sec for a 70-year-old.^{22,23} Peak velocity is an indicator of cardiac contractility. Values above the normal ranges (i.e., tall waveforms) correspond to hyperdynamic states. Values below the normal values (i.e., short waveforms) are consistent with hypodynamic states. The FTc represents left ventricular filling (i.e., preload) and systemic vascular resistance (SVR). A normal FTc is approximately 330 to 360 milliseconds. Values below this range are indicative of hypovolemia and/or systemic vasoconstriction.²⁴ Values above this range are consistent with vasodilatation.²⁴ Improving the FTc (i.e., preload) will result in greater peak velocity when applying Starling principles. Normal volunteers were monitored for their hemodynamic response to increasing infusions of positive inotropes, medications affecting afterload, and plasma removal (i.e., preload reduction) to corroborate the predicted hemodynamic measurements on the Doppler readings.²⁵ The waveform changes associated with alterations in preload, inotropy, and afterload are seen in **Figure 68-7**.

INDICATIONS

Use of EDM has been predominantly in the Intensive Care Unit and Operating Room, although it has been used in the Emergency Department for trauma resuscitation and management of septic shock.²⁵⁻²⁹ EDM allows the Emergency Physician to recognize circulatory compromise at the earliest possible time, to gain a better understanding of pathophysiologic conditions, and to provide real-time monitoring of interventions applied to patients with hemodynamic compromise or at high risk for deterioration.

CONTRAINDICATIONS

The esophageal Doppler probe is similar in size to a nasogastric tube but more rigid and less tolerated by the awake patient. Do not use EDM in patients with oropharyngeal or midface injuries. Use extreme caution in patients with portal hypertension complicated by esophageal varices. EDM is relatively contraindicated in patients with esophageal strictures, recent esophagogastric operations, or caustic ingestions because of the risk of esophageal perforation.

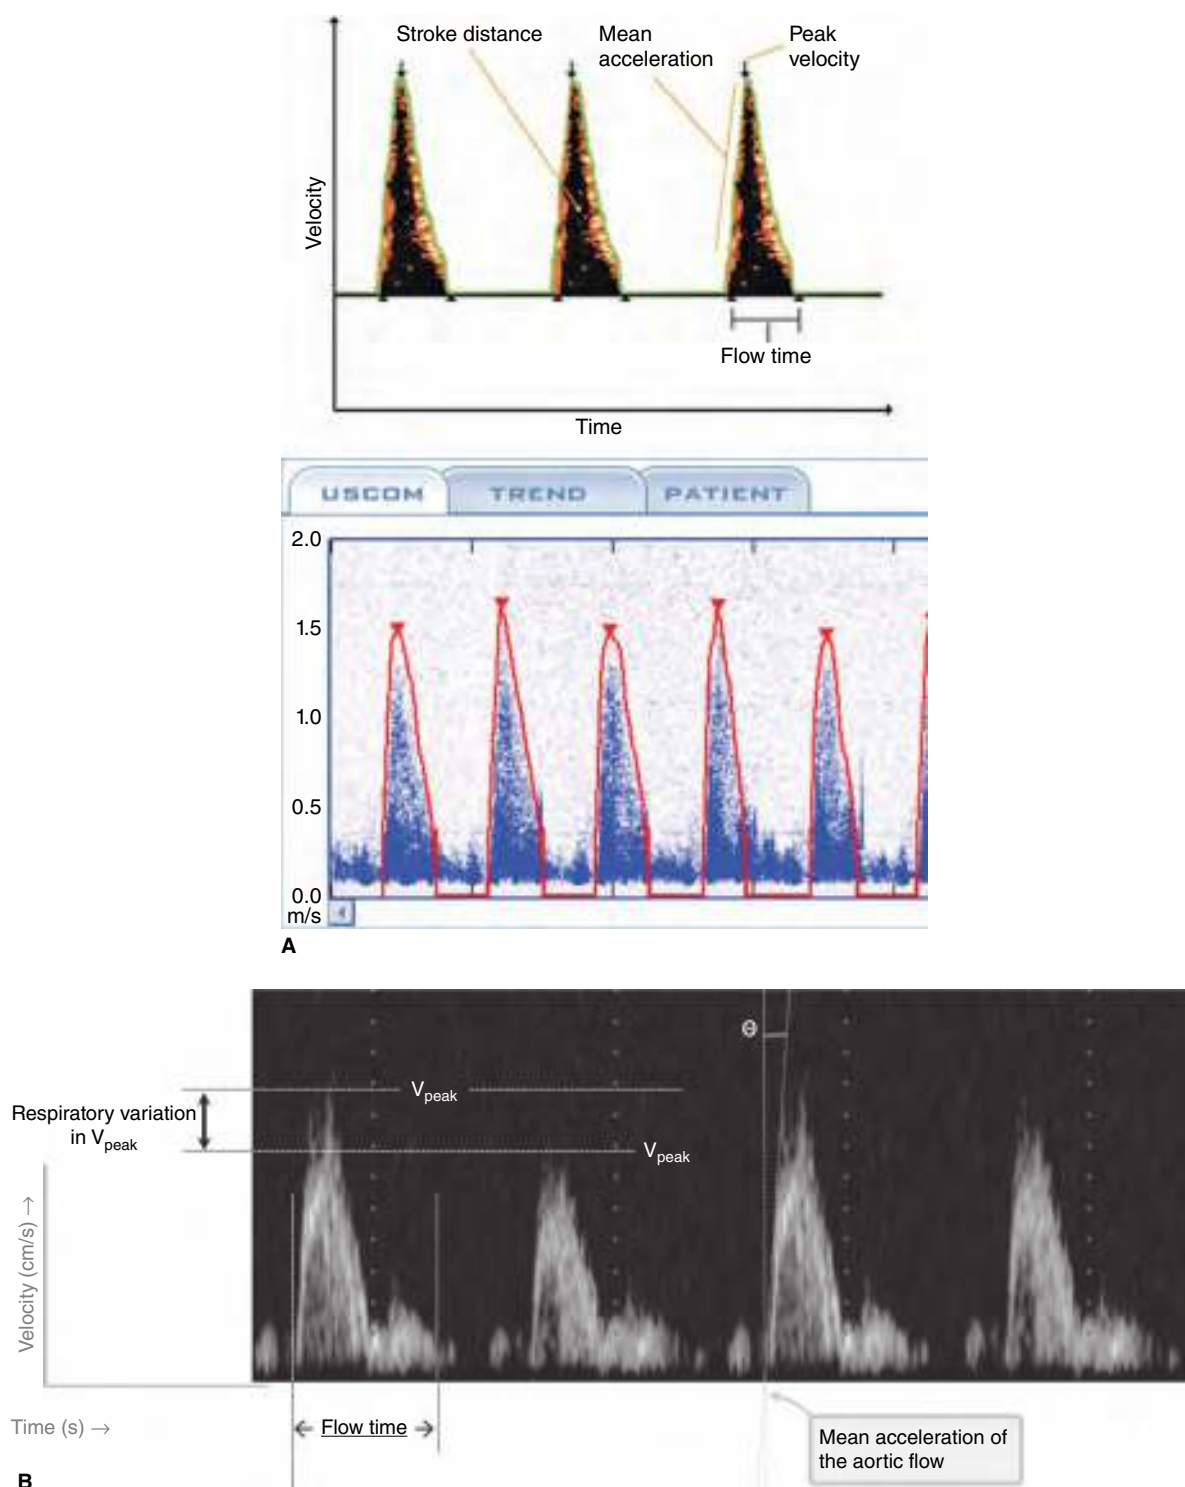

FIGURE 68-6. Velocity versus time assessed with Doppler. **A.** Top image is a graphic representation. Bottom image is a monitor view. (Used with permission from reference 19.) **B.** Doppler waveform. (Used with permission from www.derangedphysiology.com.)

EQUIPMENT

The only equipment required is the EDM machine and a probe. The beveled end of the probe emits the Doppler signal. The use of a nasal decongestant (e.g., cocaine, oxymetazoline, or phenylephrine) is recommended prior to EDM probe insertion if not contraindicated.³⁰ Some EDM probes are disposable. A sterile cover is used as a barrier method to prevent contamination with the mucosal surface of the esophagus for reusable probes. There is approximately a 1% chance

of failure with the cover. The EDM probe requires high-level disinfection after each use.³¹

TECHNIQUE

The EDM probe can be inserted via the orogastric or nasogastric approach (Chapter 75). The nasogastric approach is preferred in the awake patient. Apply a nasal decongestant prior to insertion.³² Apply lubricant to the probe. Gently insert the probe through either

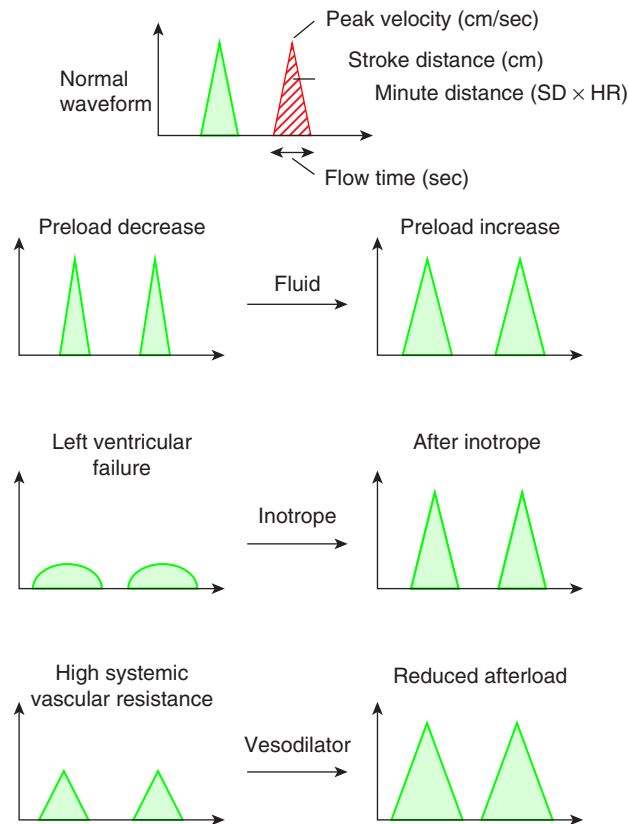

FIGURE 68-7. Waveforms associated with changes in preload, inotropy, and afterload. (Used with permission from reference 20.)

naris until it reaches the nasopharynx. **The beveled surface of the probe must be facing the posterior surface of the esophagus during insertion to capture the blood flow in the descending aorta.** Gradually advance the probe while maintaining its correct position until a distinct flow-velocity curve is obtained on the EDM output display. The image quality may be improved by slight rotation of the probe in either direction. Secure the probe to the patient once a proper waveform is obtained. Orogastric insertion is similar. Procedural sedation (Chapter 159) may help facilitate placement if the patient has difficulty tolerating placement.

AFTERCARE

Roentgenographic confirmation of EDM probe placement is not necessary, as the waveform output indicates proper positioning. An esophageal Doppler probe may be used for many days provided a proper waveform is maintained. This is in contrast to invasive CO measurement devices. Simply remove the probe in a manner similar to removing a nasogastric tube (Chapter 75) to discontinue monitoring with the EDM.

COMPLICATIONS

Minor bleeding from the nares may occur and can generally be controlled with direct pressure or packing. Sinusitis may develop with prolonged use. Prevention with nasal decongestants may minimize this complication. Chapter 75 provides a more detailed discussion of the complications associated with the use of a nasogastric tube.

SUMMARY

CO measurement obtained by EDM correlates well with that obtained by thermodilution.²⁹⁻³³ The FTc provides a measure of preload. The

peak velocity is correlated with inotropy and to a lesser extent with SVR. The device is relatively inexpensive compared to a PA catheter and has a better safety profile. EDM provides continuous CO readings that have less interrater variability than transthoracic Doppler and allows more effective trending of resuscitative interventions. Drawbacks include its poor tolerability in the awake patient and its inaccurate readings in patients with valvular abnormalities due to turbulent blood flow. Calculated measurements of the CO are derivations from these estimations because the descending aorta receives only a percentage of the total CO. EDM is not intended to serve as a replacement for the PA catheter. The EDM may prove to be an important adjunct in the resuscitation of critically ill patients and for the identification of occult hemodynamic compromise.

USCOM: ULTRASONIC CARDIAC OUTPUT MONITORING

ANATOMY AND PATHOPHYSIOLOGY

The USCOM device incorporates height-index regression equations to determine SV from the VTI and CSA of the aortic valve. The SV is then multiplied by the HR to determine the CO. The USCOM device directly measures the percent ejection time (ET%), HR, mean pressure gradient, peak velocity, and VTI. The device uses the VTI and CSA to calculate the SV, CO, and cardiac index. The machine calculates the SVR of the patient with the addition of the blood pressure and central venous pressure. The monitor displays these variables in a continuous format and allows trending with the therapies given (e.g., intravenous fluids or vasoactive agents).²²

INDICATIONS

The USCOM device has been used in the prehospital, Emergency Department, Intensive Care Unit, and Operating Room settings. It has been used in diverse patient populations (e.g., neonates, trauma patients, cardiac surgery patients, and the critically ill). There have been comparisons of the USCOM device to the PA catheter for a reference standard. Studies have evaluated the precision of Emergency Physicians using the device. The USCOM device shows a fair level of agreement with invasive methods. The trends obtained with the device may help the Emergency Physician to further differentiate shock states and assess responses to therapy.²²⁻²⁴ The device's noninvasive and portable nature makes it an attractive alternative to invasive means of CO measurement in a variety of settings.

CONTRAINDICATIONS

There are no major contraindications to using this device. Large body habitus and indwelling tracheostomy tubes may make it difficult to obtain views of the aortic root to measure the CSA. The device is best used on supine patients.

EQUIPMENT

The monitor and attached probe are the only required equipment. The transducer is curved at the tip to allow for the insonation angle to be in-line with blood flow and increase the accuracy of the measurements.

TECHNIQUE

The optimal placement of the transducer is in the suprasternal notch or the left supraclavicular space to get the aortic flow profile in the ascending aorta. There is no direct visualization of the aortic arch as would be possible in a standard US machine. The aortic CSA is

estimated by the patient's height and ideal body weight. An operator achieves confidence obtaining an adequate view after approximately 30 patients per the device manufacturer.

SUMMARY

US offers a noninvasive, portable, and cost-effective device for CO monitoring in a variety of patients and clinical settings. The CO measurements correlate well with thermodilution and have been used to assess shock states and responses to treatments. The major limitation of this technique is in patients in whom it is difficult to identify the aortic root. There is user variability based on level of experience.

PULSE CONTOUR ANALYSIS

METHODOLOGY

Otto Frank first proposed analyzing arterial pressure waveform to estimate CO in 1899.³ He used the concept of calculating the total peripheral resistance (TPR) from the time constant of diastolic aortic pressure decay. He calculated the CO from the TPR and mean arterial pressure, or MAP (i.e., $CO = MAP \div TPR$).³

The Windkessel model of blood flow was used to determine the area under the curve of the arterial waveform and has two fundamental aspects. First is conservation of mass. This means that the amount of blood entering a blood vessel is equal to the amount of blood leaving the blood vessel over the cardiac cycle. The second principle is that the compliance of the blood vessel affects the flow through it in a predictable manner. The blood vessel expands and absorbs some of the blood that would have otherwise passed through it as the pressure rises during systole. The blood vessel contracts and ejects the previously absorbed blood as the pressure drops in diastole. Wesseling and colleagues further developed the Windkessel model by incorporating the concept of impedance (i.e., the resistance to pulsatile flow). This model, known as the characteristic impedance model, incorporates the MAP and HR into the calculation of resistance.

Wesseling and colleagues subsequently developed the three-element Windkessel model, which includes peripheral resistance, compliance, and characteristic impedance. This model assumes that the impedance and compliance can be estimated by a patient's demographic data and the resistance can be calculated by incorporating the blood pressure data into the three-element model. This methodology still requires CO measurement by another method for calibration due to the variation in empiric estimates in aortic dimensions.^{25,34-36}

A variety of pulse contour analysis devices use the above models to measure CO. We will discuss the LiDCO, PiCCO, Flotrac/Vigileo, and ClearSight systems in this chapter.

LIMITATIONS

All pulse contour analysis systems use pulse pressure analysis in one form or another. **It is imperative that one has an optimal arterial waveform to analyze for a reliable estimation of the CO.** This requires a proximal arterial catheter. Use of a peripheral location results in decreased accuracy of the pulse contour.³¹ It is very important to pay close attention for overdamped or underdamped waveforms. Arrhythmias limit the accuracy of these devices because there is beat-to-beat variation in the waveform. The presence of an intraaortic balloon pump also alters the arterial waveform and limits the use of these devices. Frequent recalibration is required to ensure accurate readings during hemodynamic instability. Each system has incorporated methods to compensate for these limitations. Trend analysis in these situations may be more useful than the absolute values of CO.

LiDCO Plus AND LiDCOrapid SYSTEMS

METHODOLOGY

These systems use the PulseCO system algorithm to analyze the arterial waveform and determine continuous changes in SV. The PulseCO system incorporates the concept of characteristic impedance into its algorithm. The system modifies the characteristic impedance approach by incorporating the difference between the peripheral and central blood pressures.

The LiDCO Plus system (LiDCO, London, UK) requires calibration using a transpulmonary lithium indicator dilution technique. This requires a disposable lithium sensor, arterial line, lithium chloride, and monitor. A lithium sensor is attached to an arterial line to calibrate the system. The lithium sensor is a flow-through cell that is sterilized by gamma radiation. The lithium sensor attaches through a stopcock, and flow is restricted to 4.5 mL/min with a small peristaltic pump. Lithium chloride is injected via a peripheral or central venous line, and blood is drawn past the lithium sensor. The resulting arterial lithium concentration-time curve is recorded on a monitor (**Figure 68-8**). This value is the calculated CO for the patient and serves as the calibration point for the pulse contour algorithm.^{34,37} The arterial pressure transforms into a volume-time waveform. The raw data can be displayed if you want the numbers and to see the hemodynamic changes associated with interventions.

The LiDCOrapid uses nomograms to estimate CO (**Figure 68-9**). The key step is the conversion of blood pressure volume for aortic compliance and aortic capacitance. A patient-specific factor adjusts the aortic compliance for each patient using the PulseCO algorithm. This factor is determined by comparing the CO with the PulseCO estimate. The factor does not change over time. The device has multiple windows. The hemodynamic window shows the trends in MAP, diastolic pressure, systolic pressure, HR, and scaled SV. The dynamic preload window displays preload response values or volume status indicators (i.e., pulse pressure variation and SV variation). The blood pressure window displays the arterial pressure waveform, which is converted through the software to SV and CO. The event response window evaluates the patient response to interventions (e.g., fluid boluses and vasopressors). Finally, the data download window is used to review the patient's history.

LIMITATIONS

In addition to the general limitations of pulse contour analysis devices, the lithium chloride used for calibration of the LiDCO Plus system should not be used in patients who take lithium-containing medications, patients weighing less than 40 kg, or women in the first trimester of pregnancy. Some muscle relaxants cross-react with the

FIGURE 68-8. The LiDCO Plus monitor. (Photo courtesy of LiDCO.)

FIGURE 68-9. The LiDCOrapid monitor. (Photo courtesy of LiDCO.)

lithium sensor and make readings unreliable. This problem can be overcome by performing the calibration prior to or 5 to 10 minutes after succinylcholine, 15 minutes after pancuronium, or 15 to 30 minutes after vecuronium is administered. Rocuronium use is problematic due to the large doses administered to cause paralysis and longer plasma levels. Because the LiDCOrapid system uses estimations for the CO, it is limited in its calibration. It is contraindicated in patients with aortic regurgitation, intraaortic balloon pumps, and peripheral vascular disease. Arrhythmias provide data that cannot be analyzed by the system.

PiCCO SYSTEM

METHODOLOGY

The PiCCO system (Pulsion Medical Systems, Munich, Germany) uses a dedicated thermistor-tipped catheter to assess stroke volume on a beat-to-beat basis (**Figure 68-10**). The PiCCO algorithm includes an estimate of aortic compliance derived from analyzing the waveform distal to the aortic notch. Place a catheter in the femoral, radial, or brachial artery. The system measures aortic compliance and instantaneous pressure change integrated over systole. The advantage of this calculation is that it treats compliance as a dynamic variable that changes with time. This system does require calibration with transpulmonary thermodilution via a central venous line. The calibration is required for adjustment of individual aortic impedance. Compliance is a dynamic variable that should be recalculated every 8 hours. This system has been shown to be valid in variety of patient populations.^{36,37}

FIGURE 68-10. The PiCCO monitor. (Photo courtesy of Pulsion Medical Systems.)

LIMITATIONS

The greatest limitation of the PiCCO system is that it needs to be calibrated much more frequently in hemodynamically unstable patients. This system has been the most validated in different patient populations.

FloTrac/Vigileo SYSTEM

METHODOLOGY

The FloTrac/Vigileo System (Edwards Lifesciences, Irvine, CA) requires a proprietary FloTrac transducer. It attaches to any standard arterial line catheter and connects to the Vigileo monitor (**Figure 68-11**). This system uses a significantly different approach in determining SV than the Windkessel-based devices and does not require calibration. This system assumes that the SV is related to the standard deviation of the arterial pressure and chi. The arterial pressure (σ_{AP}) represents the relationship between pulse pressure and SV. The chi (χ) is the effect of vascular tone on waveform morphology. These variables are determined from correlations developed from a proprietary database. The standard deviation of pulse pressure

A

B

FIGURE 68-11. The FloTrac transducer connects to a standard arterial line catheter and the Vigileo monitor. **A.** The Vigileo monitor. **B.** The FloTrac transducer. (Photos courtesy of Edwards Lifesciences.)

(σ_{AP}) is sampled over a 20 second period and correlated with a “normal SV” based on patient demographic data stored in the built-in database. Impedance (χ) is determined from this data.^{34,35,38,39} The vascular compliance and resistance are determined from the arterial waveform analysis.^{34,35,38,39}

LIMITATIONS

The major limitation of the FloTrac/Vigileo system is that it may be inaccurate in patients with rapid hemodynamic changes. The algorithm has gone through significant modifications after its initial release and has subsequently shown improved performance.

ClearSight SYSTEM

METHODOLOGY

The ClearSight system (BMEYE, Edwards Lifesciences, Irvine, CA), previously known as the NexFin system, is a completely non-invasive pulse pressure analysis device that assesses pulse pressure using photoelectric plethysmography in combination with a volume clamp technique (inflatable finger cuff) (Figure 68-12). This system uses the three-element Windkessel model. The system continuously measures finger blood pressure via a cuff applied to the second, third, or fourth digit. It converts the finger blood pressure curve into a brachial arterial waveform. This system generates continuous CO measurements based on the brachial arterial waveform analysis and the patient's demographic data.^{35,40}

LIMITATIONS

The ClearSight system frequently fails to measure pressure at any of the fingers with extreme low flow in the arteries of the finger. This limits its feasibility in critically ill patients who suffer from hypoperfusion.¹⁷ This is a critical limitation because CO monitoring makes the greatest clinical impact in this patient group. This device performs adequately in healthy patients and has been recommended for use in outpatient clinics and in perioperative management. Its use in patients with suspected shock states should be cautioned until further validation.

THORACIC ELECTRICAL BIOIMPEDANCE

INTRODUCTION

Thoracic electrical bioimpedance (Z) was developed by NASA in the 1960s to monitor hemodynamic changes in astronauts. The first clinical use of bioimpedance to determine CO was by Nyöber.⁴¹

FIGURE 68-12. The ClearSight system finger cuff. (Photo courtesy of Edwards Lifesciences.)

Kubicek used the first derivative of impedance (dZ/dt) to better estimate CO calculations in astronauts and labeled it the “Kubicek equation.”^{42,43} The Sramek-Bernstein equation accounts for the non-cylindrical shape of the thorax and calibration factors compensating for patient demographics. This equation has been incorporated in the software of current bioimpedance monitoring devices such as the NCCOM3-R7 (Biomed Corp., Irving, CA). The Kubicek equation is the foundation for the CIC-1000 (Sorba Medical Systems Inc., Brookfield, WI).

The application of bioimpedance cardiography is minimally invasive, is affordable, and has very good reproducibility.⁴⁴ CO determination by thermodilution provides only a “snapshot” of a patient's hemodynamic status. Bioimpedance allows for continuous, real-time data acquisition that enables the Emergency Physician to follow a response to therapy. Such a device can be used in the Intensive Care Unit, Operating Room, and Emergency Department.

ANATOMY AND PATHOPHYSIOLOGY

The patient interfaces with the transducer through a series of disposable skin electrodes that allow for measurements of current flowing parallel to the spine. The electric current transmitted is a low-frequency (e.g., 50 to 100 kHz) and high-amplitude (e.g., 0.2 to 5.0 mA) alternating current. The voltage is sensed by pairs of electrodes at the beginning and end of the thorax (Figure 68-13). These electrodes can sense the electrocardiogram (ECG), which is necessary to determine hemodynamic variables (e.g., the ventricular ejection time determined by the distance between QRS intervals).

The electrical resistance (Z = impedance) to this current is directly proportional to the content of fluid within the thoracic cavity. The lungs and thoracic wall are of low conductance for electric current. Much of the impedance is derived from the plasma within the heart and great vessels. The average baseline impedance (Z_0) of the thorax changes due to respiration and the accumulation of interstitial fluid. Air is a poor conductor of electricity compared to plasma, and Z_0 will rise with inspiration due to increased resistance within the chest. Increased interstitial volume (i.e., pulmonary edema) will cause Z_0 to fall. The bioimpedance device will monitor Z_0 and has an inverse relationship with thoracic intravascular fluid volumes (i.e., thoracic fluid volume index [TVFI]) where $TVFI = 1/Z_0$. This index provides a way to assess central fluid status of a patient noninvasively and continuously.

The change in electrical bioimpedance (ΔZ) primarily reflects velocity and volumetric changes of aortic blood flow during each

FIGURE 68-13. An illustration of electrode placement and monitor output on the Cheetah-Nicom bioimpedance device. (Photo courtesy of Cheetah Medical.)

cardiac cycle. The first derivative of impedance (dZ/dt) is reflective of aortic blood flow. The maximum rate of change $[(dZ/dt)_{\max}]$ is proportional to the peak velocity of aortic blood flow. The timing of dZ/dt in correlation with the ECG allows for measurement of systolic time intervals such as the ventricular ejection time and the prejection period (PEP).

The SV determined by Nyober used ΔZ but was found to have excessive respiratory variability. Kubicek used dZ/dt in the SV equation, which was calculated as $SV = \text{Rho } L^2/Z_0^2 \times (dZ/dt)_{\max} \times \text{LVET}$, where Rho is the specific resistance of blood, L is thorax length, and LVET is left ventricular ejection time. Sramek proposed that $\text{Rho } L^2/Z_0^2$ be replaced by VEPT/Z_0 , where VEPT is volume of thoracic electrically participating tissue and is equal to $L^3/4.25$. This is based on the premise that the thorax is a truncated cone as opposed to a cylinder and the resistance of blood is negligible in the total resistance. Bernstein further elaborated on the equation by correcting the VEPT calculation due to differences in body habitus and using a nomogram that incorporates the patient's sex, height, and weight.⁴⁵

The bioimpedance device can be used to determine other hemodynamic variables (e.g., systolic and diastolic time intervals). The description of the cardiac cycle was pioneered by Lababidi et al.⁴⁶ The A wave is at or shortly after the beginning of the fourth heart sound and just before the ECG Q wave. The B wave occurs at the first heart sound at the apex coincident with aortic valve opening. The X wave signals aortic valve closure. The O wave occurs at mitral valve opening. The PEP represents isovolumic contraction (A→B). The LVET begins at the end of the PEP and ends at the closure of the aortic valve (B→X). The PEP and LVET compose the systolic interval. The isovolumic relaxation time (IVRT) begins when the aortic valve closes and ends on the beginning of mitral flow (X→O). The filling time (FT) is the interval between mitral valve flow and the beginning of the next cardiac cycle (O→A). The diastolic time interval comprises both the IVRT and the FT.

Contractility was first determined using bioimpedance over 30 years ago using the ratio of PEP/LVET to reflect cardiac ejection fraction.⁴⁷ Currently, there are several formulas used to calculate contractility. The Heather index $[HI = (dZ/dt)_{\max}/QZ1]$, where QZ1 = time from beginning of the Q wave to peak dZ/dt , has been shown to be the most accurate for determining contractility.^{48,49} The ability of physicians to categorize patients with congestive heart failure into those with systolic or diastolic dysfunction has been problematic. With the use of bioimpedance, Summers et al identified patients with an $HI < 5$ to have predominantly systolic dysfunction, whereas an $IVRT > 0.125$ correlated with diastolic dysfunction.⁵⁰ The use of thoracic electrical bioimpedance may facilitate the management of this difficult subset of patients.

INDICATIONS

The indications for the use of thoracic electrical bioimpedance include the management of patients with hemodynamic compromise (i.e., shock) and the recognition of occult hemodynamic compromise. Thoracic electrical bioimpedance can be used to recognize diastolic dysfunction, determine hypovolemia during tilt testing, monitor exercise tolerance, or gauge the adequacy of hemodialysis. It may become a useful adjunct in the resuscitation of critically ill patients prior to the insertion of a PA catheter due to its noninvasive nature.

CONTRAINDICATIONS

There are no contraindications to the use of a bioimpedance device. There are situations that will result in inaccurate measurements. Anything that creates noise within the system (i.e., shivering, excessive movement, and extreme obesity) will affect SV determination and measurement of other hemodynamic variables. Current

systems incorporate waveform averaging to minimize the effect of system noise. Poor skin electrode contact has been problematic, notably with excessive diaphoresis. The CIC-1000 (Sorba Medical Systems Inc., Brookfield, WI) has devised electrodes that minimize noise and optimize impedance waveform analysis.

Other limitations include valvular abnormalities and extremes in HR or rhythm. Aortic regurgitation can lead to falsely elevated SV estimates. Bradycardia less than 60 beats per minute or tachycardia over 140 beats per minute can lead to inaccurate results. Patients with paced rhythms can alter calculation of the PEP due to an altered QRS morphology. Patients with irregular rhythms will have errors in calculation of ventricular ejection time, leading to an inaccuracy in estimation of the CO. Algorithms have been created to overcome many of these flaws. It is nonetheless important to identify circumstances when thoracic electrical bioimpedance measurements may be less reliable. Extreme alterations in tissue water content, as may occur in pulmonary or chest wall edema, can modify bioimpedance analyses unrelated to changes in CO. Electrode placement can also significantly alter hemodynamic measurements. A 1 cm difference in thoracic length has been shown to result in a 10% error in stroke volume.⁵¹

EQUIPMENT

The amount of equipment necessary is limited regardless of the thoracic electrical bioimpedance device used. The device itself and the electrodes are required for measurement. Other materials needed include electrode preparation gel and a tape measure to improve accuracy of the readings.

SUMMARY

Given the growing safety concerns regarding the PA catheter, thoracic electrical bioimpedance has been found to be safe, inexpensive, and simple to use. There is good correlation between thoracic electrical bioimpedance and thermodilution-derived CO measurements.⁵² The thoracic electrical bioimpedance values tend to underestimate slightly because these are indirect measurements compared to CO obtained via a PA catheter. The ability to provide continuous and beat-to-beat output of hemodynamic data is a distinct advantage. The ability to follow trends in real time gives the Emergency Physician an opportunity to monitor disease progression as well as the response to therapeutic interventions. The ability to use thoracic electrical bioimpedance as a diagnostic tool may prove to be of great benefit in differentiating between systolic and diastolic dysfunction or identifying hypovolemia during tilt testing.

Peripheral Venous Cutdown

Jason M. Rotoli and Flavia Nobay

INTRODUCTION

Venous access in the critically ill patient is of the utmost importance. The literature regarding peripheral venous cutdowns extends back to 1940 when Keeley introduced this technique as an alternative to venipuncture in patients with shock.¹ There has been a noticeable lack of recent investigations regarding venous cutdowns. This is most likely due to the focus on central venous access with ultrasound guidance and intraosseous access. Recent editions of the Advanced Trauma Life Support (ATLS) text refer to the saphenous venous cutdown as an optional skill to be taught at the discretion of the instructor.² The importance of obtaining venous access in critically ill patients supports the need to know a wide variety of techniques in order to be successful in every situation.³ The steps outlined in 1940 by Keeley to expose and cannulate the saphenous vein remain mostly unchanged.¹

Peripheral venous access can be extremely difficult due to vascular collapse from shock, vascular injury, obesity, anatomically altered central venous sites, sclerotic veins, or cutaneous scars. Direct visualization of the peripheral vein in these patients can be more fruitful than indirect visualization.⁴ An additional advantage of the venous cutdown is that it does not interfere with concurrent resuscitative efforts.⁵ A cutdown may be the procedure of choice in resuscitating critically ill patients where resources are limited or nonexistent.

Familiarity with this procedure allows for large-bore access and the rapid infusions required in the critically ill patient.⁵ This technique can only be successfully performed if one understands the anatomy and details of venous cannulation. Practicing the cutdown technique before its critical need will help one perform optimally in the emergent setting.

ANATOMY AND PATHOPHYSIOLOGY

There are three critical areas for venous cutdowns (**Figure 69-1**). All Emergency Physicians should be knowledgeable of the anatomy of the saphenous vein at the ankle, the saphenous vein at the groin, and the basilic vein at the elbow. **The potential injury to the patient can be significant if one approaches this procedure without regard to the clinical anatomy.**

GREATER SAPHENOUS VEIN

The greater saphenous vein is the longest vein in the body. It is the ideal vein for a peripheral venous cutdown due to its anatomic regularity and superficiality (**Figure 69-2**).³ **The superficial and consistent position of the saphenous vein, in both adults and children,**

FIGURE 69-1. Common sites for peripheral venous cutdowns include the inner arm above the elbow (1), the inner thigh (2), and the inner ankle (3).

FIGURE 69-2. Anatomy of the greater saphenous vein. **A.** The subcutaneous course of the vein in the lower extremity. **B.** Detail of the greater saphenous vein at the groin.

makes this the ideal vessel for a peripheral venous cutdown.⁶ The saphenous vein begins at the medial dorsal venous arch of the foot. It passes upward and 1.5 to 2.5 cm directly anterior to the medial malleolus (**Figure 69-2A**). The saphenous vein lies just above the periosteum of the tibia at the level of the medial malleolus.⁷ It continues to ascend in the leg, along with the saphenous nerve, in the superficial fascia over the medial aspect of the leg. The vein passes posteromedially to the knee. It curves forward above the knee onto the anteromedial thigh. It passes over the falciform margin of the deep investing fascia to join the femoral vein approximately 4 cm below and 3 cm lateral to the pubic tubercle (**Figure 69-2B**).

The greater saphenous vein is easily identified at the ankle. **It will be found approximately 2.5 cm anterior and 2.5 cm superior to the medial malleolus.** It may be palpable if the patient is not hypovolemic or obese. The saphenous nerve, a branch of the femoral nerve, travels with the greater saphenous vein. It supplies sensory innervation to the skin of the medial leg and foot as far as the first metatarsal. This nerve is of minimal clinical significance and is often transected when isolating the greater saphenous vein at the ankle.

The saphenous vein in the thigh travels on the anteromedial surface and enters the fossa ovalis to join the femoral vein (**Figure 69-2B**). The femoral vein is at its largest diameter 3 to 4 cm distal to the inguinal ligament. This is approximately 2 cm distal to the approach for the placement of a femoral central venous line, at the same level where the scrotal or labial fold meets the thigh. The greater saphenous vein is also at its largest diameter in this location. The greater saphenous vein is easily isolated from the surrounding subcutaneous tissue at the level of the scrotal or labial fold meeting the thigh. **The dissection has progressed deeper than the position of the greater saphenous vein if the deep investing fascia of the thigh muscles is visible.**

FIGURE 69-3. The superficial veins of the upper extremity.

BASILIC VEIN

The basilic vein is the site of choice for a peripheral venous cutdown in the upper extremity (**Figure 69-3**). It starts from the dorsal venous arch of the hand. It ascends on the posteromedial forearm to become anteromedial on the mid-to-upper forearm. It continues to ascend to the midportion of the arm where it pierces the deep fascia. The basilic vein runs in the groove between the biceps and triceps muscles in the distal one-third of the arm. **The basilic vein can always be found in the groove between the biceps and triceps muscles.** A peripheral venous cutdown should be performed in this location. The basilic vein is more consistently found 2 cm cephalad and 1 to 2 cm lateral to the medial epicondyle of the humerus on the volar (anterior) surface of the arm. **The brachial artery and median nerve lie deep to the basilic vein in this location and are unlikely to be injured if the dissection remains superficial.**

It has been recommended that the approach to the basilic vein is through the groove between the biceps and triceps muscles in the distal one-third of the arm.^{8,9} The editor feels that locating the vein above and lateral to the medial epicondyle of the humerus will result in difficult cannulation secondary to the surrounding dense venous plexus. There is a significant risk of injury to the median antebrachial cutaneous nerve and the deep brachial artery if one tries to find and isolate the basilic vein in the middle third or proximal third of the arm. Injury to the median antebrachial cutaneous nerve will result in sensory loss to the ulnar aspect of the forearm.

BRACHIAL VEIN

Brachial vein cutdowns should not be performed in the Emergency Department. The brachial vein is small in diameter. It is

located relatively deep and would require significant and time-consuming steps to locate it. The anatomic structures surrounding the brachial vein include major arteries and nerves that can easily become injured while isolating the vein. Patients in hypovolemic shock will often not have a brachial artery pulse. This can lead to confusion as to which vessel is the artery and which is the vein.⁷ Inadvertent cannulation of the brachial artery can result in a brachial artery thrombosis and upper extremity ischemia.

AXILLARY VEIN

The axillary vein is rarely used as a site for a venous cutdown. It is contained within the axillary sheath along side the axillary artery and brachial plexus. A venous cutdown for the axillary vein can injure these structures and is associated with a high rate of complications. **It is not recommended to perform a cutdown for the axillary vein unless the Emergency Physician has specific experience with this technique.**

INDICATIONS

The primary indication for a peripheral venous cutdown is the need for venous access in a patient with no peripheral access and in whom intraosseous access or central access is not immediately obtainable or is contraindicated.² This is the ideal procedure for the intravenous drug user with no peripheral veins and scarred central access sites, the burn patient with peripheral venous collapse and scarring, the patient in cardiorespiratory arrest, or the hypovolemic trauma patient who requires definitive and lifesaving volume resuscitation.^{10,11} A unit of blood can be infused in less than 3 minutes with intravenous extension tubing inserted directly into the vein.^{5,7}

This is an excellent technique for emergent pediatric vascular access. Direct visualization of the vein will aid in cannulation of a vessel that may be collapsed secondary to undifferentiated shock from hemorrhage, hypovolemia, and/or shock. This technique should only be used after other access attempts (i.e., interosseous access, ultrasound-guided central venous access, and peripheral venous access—including scalp veins) have failed.^{2,12}

CONTRAINDICATIONS

The absolute contraindications to a peripheral venous cutdown are vascular injury, saphenous vein removal, or long bone fractures proximal to the cutdown site. Relative contraindications include infection overlying the cutdown site, bleeding disorders, or severely distorted anatomy from congenital, blunt, or penetrating trauma to the area of the cutdown or the limb. A cutdown should not be performed unless peripheral intravenous access has failed and intraosseous access equipment is not available or has failed.²

EQUIPMENT

- Povidone iodine or chlorhexidine solution*
- Local anesthetic solution*
- 10 mL syringe*
- 22 gauge needle
- #10 scalpel blade*
- #11 scalpel blade*
- #3 scalpel handle*
- Curved Kelley hemostat*
- Small mosquito hemostat*
- Vein pick

- Fine tooth forceps*
- Iris scissors
- Sharp tissue-cutting scissors
- Sterile drapes
- Towel clips
- Sterile polyethylene intravenous tubing*
- Sterile intravenous extension tubing
- Central line kit (for Seldinger method)
- Catheter-over-the-needle, 16 or 18 gauge*
- Sterile 4×4 sponges
- 5 mL syringe
- 18 gauge needles
- Self-retaining skin retractors
- Small rake, two
- Needle driver*
- Silk suture, 3-0 and 4-0*
- Injectable sterile saline
- Intravenous tubing and solution
- Wound dressing supplies
- Antibiotic ointment

The comprehensive list of equipment is listed above (**Figure 69-4**). The equipment is contained in a cutdown kit. Many Emergency Departments do not have cutdown kits available. The basic equipment (**Figure 69-5**) denoted by an asterisk is contained in a chest tube tray or thoracotomy tray. Neither **Figure 69-4** nor **Figure 69-5** shows the intravenous tubing, normal saline bag, and dressing supplies that are available in every Emergency Department.

PATIENT PREPARATION

The patient is usually in extremis and positioned supine if a peripheral venous cutdown is to be performed. They may be in the Trendelenburg position, although this is not ideal for the procedure. Secure the selected extremity to the bed with a restraint, tape, or an assistant holding it in place. **Perform a cutdown in as sterile a manner as possible.**

Identify the landmarks for the procedure. Clean the skin of any dirt and debris. Anesthetize the area of the cutdown if the patient

FIGURE 69-4. Comprehensive equipment.

FIGURE 69-5. Basic equipment.

is conscious. Infiltrate local anesthetic solution into the subcutaneous tissue where the incision will be made. Prepare the skin with povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to isolate a surgical field. Collect and set up all the required equipment on a bedside table covered with a sterile drape.

TECHNIQUES TO ISOLATE THE VEINS

The technique of cannulation is the same regardless of the vein chosen. The methods to isolate the saphenous vein and the basilic vein will be discussed in this section. A discussion of the different techniques to cannulate the isolated vein will be presented in the following section.

GREATER SAPHENOUS VEIN ISOLATION AT THE ANKLE

The saphenous vein is reliably found and easily isolated at the ankle (**Figures 69-6** and **69-7**). Extend and externally rotate the lower extremity. Identify the medial malleolus of the tibia. Find the location 2.5 cm anterior and 2.5 cm superior to the medial malleolus. The greater saphenous vein can often be found at this site (**Figures 69-6A** and **69-7A**). Alternatively, place the index and middle fingers at the level of the malleolus. The vein will be found two finger breadths cephalad and two finger breadths anterior to the medial malleolus. The vein may be palpable if the patient is not hypovolemic or obese. The vein may be visualized in patients with thin skin, superficial veins, minimal subcutaneous tissue, or dark vessels.

Stretch the skin taught over the distal tibia with the nondominant hand (**Figures 69-6B** and **69-7B**). Note the position of the hands in the illustration. **The nondominant hand is placed with the fingertips pointing toward the Emergency Physician.** This will prevent inadvertent injury while making the skin incision. Transversely incise the skin overlying the great saphenous vein using a #10 scalpel blade. Make the incision from the anterior tibial border to the posterior tibial border after appropriate anesthesia (**Figures 69-6B** and **69-7B**). **This incision should be superficial so that the subcutaneous tissue is barely exposed.** A deep incision may inadvertently transect the vein causing significant bleeding, difficulty visualizing the surgical field, and difficulty completing the procedure due to subcutaneous venous retraction. Apply tension to the skin on either side of the incision to expose the underlying structures. This can be

FIGURE 69-6. Artist illustration of isolation of the greater saphenous vein at the ankle. **A.** Identifying the vein. **B.** A transverse skin incision is made from the anterior to the posterior border of the medial tibia. **C.** The tip of a curved hemostat is scraped along the tibia and then rotated 180°. **D.** The hemostat is spread to separate the tissues. **E.** A straight hemostat is inserted between the jaws of the curved hemostat to elevate the vein. **F.** The curved hemostat has been removed.

accomplished with the nondominant hand, a self-retaining retractor, or skin rakes held by an assistant.

Isolate the greater saphenous vein.⁸ This may be difficult in some patients in shock or patients in the Trendelenburg position as the vein may be poorly perfused. Grasp and hold a curved hemostat or a Kelly clamp with the tip facing downward. Insert the hemostat along the posterior border of the tibia and scrape the tip anteriorly along the tibia. If done properly, all the tissue between the skin and

the tibia will be above the hemostat. If not visible, cautiously blunt dissect with the curved hemostat down to the vein. When identified, insert the hemostat under the vein and rotate the hemostat 180°. The tip of the hemostat will be facing upward (**Figures 69-6C and 69-7C**). Widely open the arms of the hemostat (**Figures 69-6D and 69-7D**). This will open the jaws of the hemostat and separate the saphenous vein from the saphenous nerve and fibrous strands of connective tissue. The saphenous vein should be visible between

FIGURE 69-7. Isolation of the greater saphenous vein at the ankle in a cadaver. **A.** Identifying the vein. The long blue line is the greater saphenous vein (GSV). **B.** A transverse skin incision is made. **C.** The greater saphenous vein is isolated. **D.** The hemostat is spread to separate the tissues. **E.** A straight hemostat is inserted between the jaws of the curved hemostat to elevate the vein. **F.** The curved hemostat has been removed.

the jaws of the hemostat. If there is difficulty identifying the vein, squeeze the foot to fill the vein with blood. Insert a straight hemostat or a Kelly clamp between the jaws of the curved hemostat and below the greater saphenous vein (**Figures 69-6E and 69-7E**). Remove the curved hemostat to leave the straight hemostat elevating the greater saphenous vein (**Figures 69-6F and 69-7F**). The straight hemostat will be useful as a “cutting board” to later transect the vein and allow more control of the vein.

An alternative technique to isolate the vein is used by some physicians. **This technique is not recommended by the editor but is briefly described for the sake of completeness.** Make the transverse skin incision. Place the jaws of a curved hemostat parallel to the greater saphenous vein. Open the arms of the hemostat to allow the jaws to dissect through the subcutaneous tissue. Continue placing the hemostat and opening the jaws until the vein is isolated. This technique is harder to perform because the vein is less likely to be identified given the white background of the periosteum.^{1,12,13} In addition, this technique takes significantly longer to find and isolate the vein.

GREATER SAPHENOUS VEIN ISOLATION AT THE GROIN

The groin vasculature offers the potential for massive infusion of blood or fluids in a matter of minutes.⁵ These vessels are closer to the central circulation and large enough to easily accommodate intravenous tubing cut off at a 45° as a catheter. The greater saphenous vein is superficial at the groin and lies in a meshwork of subcutaneous tissue. It is superficial to the femoral artery and vein. The saphenous vein travels on the anteromedial surface of the thigh and enters the fossa ovalis to join the femoral vein (**Figure 69-2B**). The greater saphenous vein is at its largest diameter 3 to 4 cm distal to the inguinal ligament. This is approximately 2 cm below the site for placement of a femoral central venous line and level with where the scrotal or labial fold meets the thigh.

Identify the location where the scrotal or labial fold meets the thigh (**Figure 69-8**). Identify the lateral edge of the mons pubis. Identify the point where a vertical line from the lateral edge of the mons pubis meets a horizontal line from the scrotal/labial fold. Make a transverse, medial to lateral, incision with a #10 scalpel blade on

FIGURE 69-8. Isolation of the greater saphenous vein at the groin. The skin incision should begin where the scrotal or labial fold meets the thigh. Extend the incision laterally until it meets a vertical line from the lateral edge of the mons pubis.

the patient's thigh starting where the scrotal or labial fold meets the thigh after appropriate anesthesia. Extend the incision laterally until it meets the vertical line from the lateral edge of the mons pubis.

Dissect the subcutaneous tissue to locate the greater saphenous vein. Place the jaws of a curved hemostat parallel to the greater saphenous vein. Open the arms of the hemostat to allow the jaws to dissect through the subcutaneous tissue. Continue placing the hemostat and opening the jaws until the vein is isolated. **The dissection is too deep if the deep investing fascia or the muscle bellies of the thigh muscles are encountered.** Stop, reidentify the landmarks, and adjust the skin incision and dissection as necessary.

The subcutaneous tissues can alternatively be bluntly dissected using 4×4 gauze squares. Grasp two or three gauze squares in each hand. Put the fingertips of both hands, covered with gauze, in the center of the incision. Move the hands in opposite directions (i.e., cephalad and caudad) while scraping the subcutaneous tissue with the gauze. Reapply the hands in the incision and repeat the motion until the greater saphenous vein is exposed. This technique applies pressure parallel to the greater saphenous vein and will not injure the vein.

BASILIC VEIN ISOLATION AT THE ELBOW

The basilic vein may be used for a peripheral venous cutdown. This is often performed when the greater saphenous vein cannot be accessed due to lower extremity amputation, deformity, injury, or trauma, or if it has been used previously (e.g., in a coronary bypass). This site is not ideal as it may interfere with resuscitative efforts while the basilic vein is being exposed. The basilic vein is consistently found 2 cm cephalad and 1 to 2 cm lateral to the medial epicondyle of the humerus on the volar surface of the arm. It may also be found in the groove between the biceps and triceps muscles. There is controversy in the literature as to where the incision for the basilic vein cutdown should be performed. The simple answer is that if one fails in isolating the vein in one location, make an incision in the second location to isolate the vein.

Position the patient to allow exposure of the basilic vein. Abduct the patient's arm 90° with the elbow flexed 90° and the palm facing upward (**Figure 69-9**). This positioning is required to access the basilic vein at either location.

Identify the point 2 cm cephalad and 2 cm lateral from the medial epicondyle of the humerus. This is the location of the basilic vein. Make a 4 to 6 cm transverse incision with a #10 scalpel blade centered on the reference point after appropriate anesthesia. The incision should only cut through the epidermis. Bluntly dissect the subcutaneous tissue with a curved hemostat or 4×4 gauze squares, as described previously, to locate the basilic vein. **The dissection is too deep if the brachial artery, median nerve, or muscle fibers are encountered.** Stop, reidentify the landmarks, and adjust the skin incision as necessary.

Alternatively, the basilic vein can be isolated in the middle of the distal third of the arm. Palpate the groove between the biceps and triceps muscles. This is the location of the basilic vein. Make a 4 to 6 cm horizontal incision centered about the groove after appropriate anesthesia. Bluntly dissect with a curved hemostat until the vein is located. The basilic vein is superficial to the muscle fascia and the brachial artery.

TECHNIQUES FOR CANNULATION OF THE VEIN

There are numerous techniques to cannulate a vein after it has been isolated. Any of the following techniques can be used to cannulate the greater saphenous vein or the basilic vein. The rapid and definitive cannulation of the vessel is the primary goal and not the chosen technique.

FIGURE 69-9. Isolation of the basilic vein.

GENERAL ACCESS TO THE VEIN

Isolate the chosen vein as described previously. Place a straight hemostat or a Kelly clamp under the midportion of the vein (**Figure 69-10A**). Slightly elevate the hemostat. Pass a silk suture under the vein at its proximal end and a second silk suture at its distal end (**Figures 69-10B and 69-11A**). Grasp the silk sutures with a hemostat to maintain the position of the tie and to allow for manipulation of the vein. Tie the distal suture to occlude inflow of blood from distal veins (**Figures 69-10C and 69-11B**). **Do not cut either of these two sutures. The proximal suture will be left untied to allow for control and manipulation of the vein.**

Incise the vein. Grasp the hemostat holding the proximal suture with the nondominant hand. Raise the hemostat to flatten the vein and prevent back bleeding. Make a small incision through a third to half of the vein with the tip of a #11 scalpel blade (**Figures 69-10D, 69-11C, and 69-11D**).^{12,14} **Do not cut the entire vein as this will cause significant bleeding and loss of the proximal end. If the incision is too large, greater than one-half the vein's diameter, the vessel may be torn completely and retract from the surgical field.^{12,14} If the incision is too small, the catheter will enter a false lumen in the vein wall.^{12,14}** The straight hemostat below the vein will act as a “cutting board” and prevent injury to underlying structures from the scalpel blade. As an alternative, the jaws of the straight hemostat can be opened and the vein cut with an iris scissors (**Figure 69-10E**).

FIGURE 69-10. Artist illustration of general access to the vein. **A.** The vein has been isolated. **B.** A silk suture has been placed proximally and distally around the vein. **C.** The distal suture is tied. **D.** An incision is made through the vein with a #11 scalpel blade. **E.** Alternatively, the hemostat is opened and an iris scissors is used to cut the vein.

SELDINGER TECHNIQUE

The traditional technique for peripheral venous cannulation can use the Seldinger method.^{13,15} This technique will insert the catheter as if cannulating a central vein (Chapter 63). The required equipment can be found in a prepackaged central venous line access kit. This includes the guidewire, introducer sheath, dilator, and the venous catheter. This technique can accommodate a large caliber line, such as an 8 or 9 French introducer sheath. This technique may save 1 to 2 minutes on cannulation time by eliminating the ligature and tie off steps.

Isolate the chosen vein as described previously. Place a straight hemostat or a Kelly clamp under the midportion of the vein and open the jaws (**Figure 69-12A**). Insert the catheter-over-the-needle into the vein (**Figure 69-12A**). Stop advancing the catheter-over-the-needle when a flash of blood is seen in the needle hub. **Be cautious not to puncture the posterior wall of the vein.** Remove the straight clamp. Advance the catheter into the vein while securely holding the needle. Remove the needle. Insert the guidewire through the catheter. Remove the catheter by backing it out over the guidewire, which

will remain in the vein. Place the dilator through the introducer sheath. Feed the dilator-introducer sheath unit over the guidewire (**Figure 69-12B**). Advance the unit into the vein with a twisting motion while securely holding the guidewire (**Figure 69-12C**). Continue to advance the unit until the hub of the introducer sheath is just above the vein (**Figure 69-12D**). Remove the guidewire and dilator as a unit (**Figure 69-12D**). Attach intravenous tubing to the hub of the introducer sheath and begin instilling fluids.

MODIFIED SELDINGER TECHNIQUE

An alternative and quicker method can be used to insert the introducer sheath into the vein (**Figure 69-13**). Isolate the chosen vein as described previously. Place a straight hemostat or a Kelly clamp under the midportion of the vein and open the jaws (**Figure 69-13A**). Assemble the unit by placing the dilator through the sheath and insert the guidewire through the dilator (**Figure 69-13B**). The guidewire should protrude 3 to 4 mm beyond the tip of the dilator. Make an incision in the lateral half of the vein (**Figure 69-13C**). Hold the proximal

FIGURE 69-12. The Seldinger technique of venous cannulation. **A.** The vein has been isolated. The catheter-over-the-needle is inserted into the vein. **B.** A guidewire has been placed into the vein. The dilator and sheath are fed over the guidewire. **C.** The dilator and sheath are advanced into the vein with a twisting motion. **D.** The guidewire and dilator are removed as a unit.

guidewire and sheath. Insert the distal guidewire into the vein. Continue to insert the entire unit with a twisting motion into the vein (**Figure 69-13D**). Continue to advance the unit until the hub of the introducer sheath is just above the vein. Remove the guidewire and dilator as a unit (**Figure 69-13E**). Attach intravenous tubing to the hub of the introducer sheath and begin instilling fluids.

SURGICAL TECHNIQUE USING INTRAVENOUS TUBING

Use an assistant to prepare the intravenous tubing. Attach sterile intravenous polyethylene tubing to a bag of sterile saline. Cut the angiocatheter attachment hub off the end of the tubing at a 45° angle. Some authors suggest using a feeding tube instead of

FIGURE 69-13. The modified Seldinger technique of venous cannulation. **A.** The vein has been isolated. **B.** The dilator, guidewire, and sheath are assembled as a unit. **C.** An incision has been made in the vein. **D.** The unit is inserted into the vein, guidewire first. A twisting motion will aid in its insertion. **E.** The guidewire and dilator are removed as a unit.

intravenous tubing.¹² This is not recommended. Intravenous tubing is ubiquitously available. The rounded tip of the feeding tube may be more difficult to advance into the vein. The only advantage to using a feeding tube is that the rounded tip has less chance of puncturing the posterior wall of the vein.

Insert the angled edge of the intravenous tubing into the vein. Gently relax the tension on the proximal suture to allow the vein to open. Advance the intravenous tubing 2 to 3 cm into the vein (**Figure 69-14A**). There is often considerable difficulty advancing the catheter. **Do not force the catheter through the vein as it is very delicate.** Troubleshoot by removing the catheter and make sure that the lumen of the vein has been cannulated. This is sometimes difficult to accomplish. If so, have an assistant control the proximal suture. Use a mosquito hemostat to grasp the cut edge of the vein and lift upward to expose the vein's lumen and insert the intravenous tubing (**Figure 69-14B**). A mosquito hemostat may be too large to grasp the cut edge of small veins. Insert a vein

FIGURE 69-14. Venous cannulation using intravenous tubing. **A.** The tubing is inserted into the vein and advanced. **B.** A mosquito hemostat can be used to grasp the vein and hold it open while the tubing is inserted. **C.** For small veins, a vein pick or 18 gauge needle with the tip bent can be used to hold open the vein. **D.** The proximal suture is tied to secure the tubing.

pick or an 18 gauge needle with the tip bent into a 90° angle into the lumen of the vein (**Figure 69-14C**). Lift upward to expose the vein's lumen and insert the intravenous tubing.

Palpate the posterior aspect of the vein after inserting the intravenous tubing for penetration of the catheter. **The catheter must be removed if it penetrates through the posterior wall of the vein.** Release the proximal suture and allow the intravenous fluid to flow into the vein if the tubing has not penetrated the posterior wall of the vein. Tie the proximal suture to secure the intravenous tubing within the vein if the fluid flow is unobstructed and the fluid is not extravasating into the surrounding tissues (**Figure 69-14D**). **Do not tie the suture too tight to occlude the tubing.** Tying the suture too tightly may also result in a thrombosis.¹¹ If the tubing is within the lumen of the vein and the fluid is not flowing, the tubing may be against a venous valve. Gently advance the catheter 2 to 3 mm or withdraw it 2 to 3 mm and observe the fluid for flow.

An alternative method is available (**Figure 69-15**). Expose the vein as described previously. Grasp and elevate the distal skin edge with a hemostat. Make a stab incision with a #11 scalpel blade approximately 1 cm distal to the previously made skin incision (**Figure 69-15A**). **Use caution not to cut the underlying vein.** Insert the intravenous tubing through the stab incision and pull it through the skin incision. Incise the vein and insert the tubing as described previously. This allows the tubing to be tunneled through the subcutaneous tissue before cannulating the vein (**Figure 69-15B**).

INTRAVENOUS CATHETER TECHNIQUE

This technique involves the insertion of a standard, 16 to 18 gauge, intravenous catheter-over-the-needle into the vein (**Figures 69-16 and 69-17**). This technique is sometimes referred

FIGURE 69-15. Alternative technique of venous cannulation with intravenous tubing. **A.** The distal skin edge is elevated. A #11 scalpel blade is used to make a stab incision in the skin and subcutaneous tissues. **B.** The tubing is fed through the stab incision and into the vein.

FIGURE 69-16. Artist illustration of insertion of the catheter-over-the-needle. **A.** Insertion through the incision and into the vein. **B.** Insertion through the skin and into the vein.

A

B

C

to as the mini-cutdown. The vein is cannulated under direct visualization through a skin incision. This technique will insert the catheter as if cannulating a peripheral vein (Chapters 59 and 61). This method is very quick, provides a more secure cannulation, and potentially decreases the chance of infection.

Isolate the chosen vein as described previously. Place a straight hemostat or a Kelly clamp under the midportion of the vein and open the jaws (**Figure 69-16A**). Insert the catheter-over-the-needle into the incision and the vein under direct visualization (**Figures 69-16A and 69-17A**). Stop advancing the unit when a flash of blood is seen in the needle hub. Advance the catheter into the vein while removing the hemostat. Advance the catheter until the hub is just above the vein (**Figure 69-17B**). Remove the needle. Attach intravenous tubing to the catheter hub and begin instilling fluids. Gently tie the proximal suture to secure the catheter within the vein.

Alternatively, insert the catheter-over-the-needle through the skin, 1 cm distal to the distal skin edge until the tip is visualized in the incision (**Figures 69-16B and 69-17C**). Insert the catheter-over-the-needle into the vein under direct visualization. Stop advancing the unit when a flash of blood is seen in the needle hub. Advance the catheter into the vein while removing the straight clamp. Advance the catheter until the hub is against the skin (**Figure 69-17C**). Remove the needle. Attach intravenous tubing to the catheter hub and begin instilling fluids. The advantage of this method is that the catheter goes through the skin, which will stabilize the catheter and prevent it from becoming dislodged.

AFTERCARE

It is not necessary to close the skin incision immediately after the cut-down. Place a saline moistened gauze over the incision site. Wrap a sterile dressing around the extremity and the skin incision site. The skin incision must be closed after more definitive access has been obtained. If the intravenous tubing was inserted as above, the skin incision will be sutured closed and the tubing will exit the incision. Some feel this may allow access of bacteria through the wound and into the underlying vein.

Secure the cutdown more permanently if the patient survives the episode for which a venous cutdown was performed. Suture the wound closed with simple interrupted 4-0 nylon sutures (**Figures 69-18 and 69-19**). Place a suture through the skin, wrap it around the catheter, and tie it to secure the catheter to the skin (**Figure 69-18**). Apply antibacterial ointment to the incision, the sutures, and the site where the catheter exits the skin. Secure the intravenous tubing (**Figure 69-19B**). The catheter can be looped around the toe, for a cutdown at the ankle, and secured with gauze wrap or an elastic wrap (**Figure 69-20A**). The catheter can be secured by taping it to the skin (**Figures 69-19B and 69-20B**). The limb can be immobilized on a board, after the catheter is secured at the ankle or elbow, for added security from inadvertent dislodgement of the catheter (**Figure 69-20C**).

COMPLICATIONS

The complications of a peripheral venous cutdown include arterial injury, nerve injury, phlebitis, thromboembolism, wound dehiscence, and wound infection. The incidence of complications ranges from 2% to 15%.^{16,17} The true complication rate is difficult to report given the high mortality rate in patients undergoing this procedure due to the primary problem (e.g., hypovolemia, sepsis, shock, or trauma). The knowledge of the local anatomy and the technical aspects of the various cutdown techniques may avoid arterial, venous, and nerve injury. The other complications may be reduced by removal of the catheter within 12 hours after placement.¹⁷

FIGURE 69-18. The skin incision is closed with interrupted 4–0 nylon sutures. The catheter exits the original incision (**A**) or a separate skin incision (**B**).

It can take time to insert the tubing or central line catheter into the vein.¹⁸ The patient can deteriorate very quickly within this time. The cutdown procedure can be quicker if using a vein pick to open the cut vein, an 18 gauge needle prebent to 90° to open the cut vein, or a catheter-over-the-needle (i.e., mini-cutdown technique).

PHLEBITIS

It is generally agreed that phlebitis is more likely to occur in the lower extremity than the upper extremity although there is little data to support this. Phlebitis, an inflammation of the vein, usually results from prolonged catheterization. It may be seen within hours of catheter placement to 18 days after the removal of the catheter.¹⁷ In 1960, Bogen looked at 234 ankle cutdowns and found a 4% phlebitis rate.¹⁹ He felt this was secondary to infection. The strength of the correlation was attributed to a previous unrelated study that found *Staphylococcus aureus* on almost all catheter tips in patients with phlebitis as opposed to catheter tips in patients without phlebitis. These cases of phlebitis all resolved without the use of antibiotics suggesting an inflammatory, rather than infectious, process to be the more likely etiology. Moran et al cultured 89 cutdown sites and observed that the pathogenic species causing infection were *S. aureus*, *Enterococcus*, and *Proteus*.¹⁷ These organisms were cultured more frequently in patients who had cutdowns that were left in place for longer periods of time. They did not find a correlation between infection and phlebitis and postulated that phlebitis was due to irritation of the vein wall by the catheter.¹⁷ **It is clear from these studies that early removal of the intravenous catheter**

A

B

FIGURE 69-19. The skin incision is closed in a cadaver (**A**) and covered with a clear dressing (**B**).

within 12 hours of placement will significantly decrease the incidence of phlebitis.

INFECTION

It was not found that prophylactic antibiotics reduced infection rates.¹⁷ The application of daily topical antibiotic ointment reduced positive local wound cultures from a rate of 78% to 18%. Collins et al studied polyethylene catheters and found a 2% bacteremia rate and a 1% death rate from *Pseudomonas* species in debilitated patients.²⁰ In 1988, Rhee et al found only one case of cellulitis in their study of 78 patients.¹⁵ **It is clear from these studies that early removal of the intravenous catheter within 12 hours of placement will significantly decrease the incidence of infection and subsequent complications.** Sterile technique is encouraged with this procedure to minimize complications related to infection.

ASSOCIATED INJURIES

Injury to adjacent arteries, nerves, and veins can be avoided by a detailed understanding of the local anatomy and careful procedural

FIGURE 69-20. Securing the intravenous catheter. **A.** The catheter is looped around the great toe, for an ankle cutdown, and secured with gauze or elastic wrap. **B.** The catheter is secured with tape. **C.** The ankle or elbow can be secured to a board for additional security.

technique. Aggressive and forceful dissection without an understanding of the anatomy or the procedure will increase the incidence of complications. Injury to adjacent cutaneous nerves is unavoidable and inconsequential. Venous spasm, which causes nonuniform acceptance of the intravenous extension tubing, may also occur.¹⁷

SUMMARY

The peripheral venous cutdown is an excellent technique for rapid fluid or blood product infusion. This is usually performed when other methods of venous access are unavailable or have failed. It is

a relatively simple procedure. If learned properly, it can be lifesaving in the critically ill or injured patient. It is imperative to understand the relevant local anatomy and identify the clinical landmarks before this procedure is performed. Strict adherence to sterile technique and the early removal of the catheter will decrease the rate of infection and other complications.

Intraosseous Infusion

Beech S. Burns, James Heilman, and O. John Ma

INTRODUCTION

Obtaining peripheral vascular access in the critically ill patient may be difficult and time consuming. The vascular collapse that may accompany severe dehydration or a cardiac arrest can be profound and delay administration of essential therapies. Pediatric patients present a challenge due to the small size of their peripheral veins and the increased subcutaneous tissue. Administration of endotracheal medications may not provide rapid and reliable drug

absorption during a cardiorespiratory arrest.^{1,2} Establishing vascular access quickly in these cases can be lifesaving.

Intraosseous (IO) access was first described in 1922 by Dr. Drinker. He referred to the medullary cavity as a “noncollapsible vein” that can be used for obtaining rapid vascular access. IO access for pediatric use was introduced in 1941, and the first IO blood transfusion was documented in 1942.³ The IO route of venous access did not enjoy widespread use for several reasons. The equipment for performing an IO at the time was crude and did not improve until the 1970s. The saphenous venous cutdown technique was developed and gained popularity as an alternative method for obtaining vascular access when attempts at peripheral vein cannulation failed. Finally, the development of plastic, disposable, and single-use intravenous (IV) catheters revolutionized the technique of IV access and made this modality the preferred primary method.

IO access experienced a resurgence in popularity in the mid-1980s as its utility in the care of the critically ill patient was increasingly recognized.^{4,5} IO access may be used to administer blood products, drugs, and fluids during cardiopulmonary resuscitation, a scenario where peripheral IV access may be particularly challenging. This procedure was more widely deployed in the care of pediatric patients due to the increased difficulty of obtaining vascular access in profoundly ill children. The IO placement time was slightly longer in pediatric cardiac arrest than peripheral venous access (3.0 versus 4.7 minutes), but the IO success rate was significantly higher (83% versus 17%).⁶ IO infusion has been shown to be safe and effective in neonates and may be more rapidly obtainable than umbilical venous catheters.^{7,8} The use of IO devices in pediatric patients has become widespread, associated with high success rates, and associated with a low incidence of complications.⁷⁻⁹ IO access will cause metal artifact in most cases if obtaining a computed tomography (CT) scan of the area.¹⁰

IO access has been increasingly used in the resuscitation of adult patients when vascular access is unobtainable. It has become the first-line option for cardiac arrest patients.¹¹⁻¹⁴ IO access has become an invaluable procedure for prehospital providers and has repeatedly been shown to be safe and effective.¹⁴⁻¹⁷ The newer commercially available powered devices make penetrating the adult bone cortex much less difficult. Several prehospital studies have demonstrated success rates for IO placement of $\geq 90\%$.^{17,18} Emergency Medical Services systems have integrated IO devices into their vascular access protocols, and Emergency Departments routinely stock these devices.¹⁷ A meta-analysis demonstrated overall success rates using a commercially available IO drill of about 90%, underscoring the fact that this modality can be used effectively and in all patients.¹⁸

ANATOMY AND PATHOPHYSIOLOGY

Long bones are composed of a dense outer cortex and inner soft, spongy (i.e., cancellous) bone (**Figure 70-1**). The nutrient artery supplies the bone with a rich vascular network. It pierces the cortex and divides into ascending and descending branches that further divide into arterioles and then capillaries. Venous drainage from the capillaries into the medullary venous sinusoids, located at the proximal and distal portions of the long bone, flows into the central venous channel located in the shaft of the long bone.¹⁹

The IO needle is inserted through the cortex and into the bone marrow (i.e., medullary) cavity of a long bone. Numerous anatomic sites can be used to access the medullary cavity. The most traditional site, which has been favored in pediatric patients, is the flat anteromedial surface of the proximal tibia (**Figure 70-2**). The distal tibia just above the medial malleolus is one of the preferred sites in adult patients (**Figure 70-3**). In the adult, it is easier to penetrate the cortex of the medial malleolus than the thicker cortex of the proximal tibia. Other sites for IO access include the flat anterior surface

FIGURE 70-1. Venous anatomy of a long bone.

FIGURE 70-2. The proximal tibia is the traditional site used in pediatrics for IO access. The ⊗ represents the site of IO needle insertion.

FIGURE 70-3. The distal tibia is one of the preferred sites for IO access in adult patients. The ⊗ represents the site of IO needle insertion.

FIGURE 70-4. The distal femur is an alternative site for IO access. The ⊗ represents the site of IO needle insertion.

of the distal femur (**Figure 70-4**), the anterolateral surface of the proximal humerus (**Figure 70-5**), and the superior one-third of the sternum.^{10,20-25}

Crystalloid infusion rates through an IO line vary depending on the bone accessed and the pressure of the fluid being administered. Under 300 mmHg of pressure, the sternum, proximal humerus, and proximal tibia have the following respective observed rates: 93, 70, and 30 mL/min.²⁶ The humerus provided greater flow rates than the tibia at all infusion pressures.²⁷ The flow rate of the proximal tibia was greater than the distal tibia at all infusion pressures.²⁸ Infusion rates approximate 10 to 20 mL/min using gravity.^{26,29,30} Fluids and medications administered through an IO line are rapidly absorbed into the systemic circulation, and multiple studies have demonstrated similar effectiveness between IO and IV routes.^{31,32} Succinylcholine has been effectively infused by the IO route for muscle paralysis prior to endotracheal intubation.³³ Sodium bicarbonate was shown to have superior buffering capacity when administered via an IO line than by peripheral IV.³⁴ It is unclear, however, whether

FIGURE 70-5. The proximal humerus is an alternative site for IO access in the adult. The ⊗ represents the site of IO needle insertion.

TABLE 70-1 Some of the Medications and Fluids Shown to Work Administered Through an IO Line*

Medications		
Adenosine	Dopamine	Morphine
Alteplase	Ephedrine	Naloxone
Amiodarone	Epinephrine	Norepinephrine
Anesthetics	Factor IX complex-human	Pancuronium
Antibiotics	Fentanyl	Phenobarbital
Antitoxins	HL-6 oxime	Phenytoin
Atracurium besylate	Heparin	Pralidoxime
Atropine	Human growth hormone	Propranolol
Calcium chloride	Hydroxocobalamin	Sodium bicarbonate
Calcium gluconate	Insulin	Succinylcholine
Contrast media	Isoproterenol	Tenecteplase
Dexamethasone	Ketamine	Thiopental
Diazepam	Levarterenol	Tranexamic acid
Diazoxide	Lidocaine	Vasopressin
Dicobalt edetate	Lipid emulsion	Vecuronium
Digoxin	Lorazepam	
Dobutamine	Mannitol	
Fluids		
Blood products	Lactated Ringer's solution	Sodium chloride solutions
Dextrose solutions	Packed red blood cells	
Iodinated contrast agents	Plasma

medications with extremely short half-lives (e.g., adenosine) are as effective when compared to administration via more central IV access.^{35,36} Medications and fluids that may be administered by the IO route are listed in **Table 70-1**.³⁷⁻⁵⁶ **The medication concentrations, dosages, and infusion rates through an IO line are the same as those through a peripheral IV line.**

INDICATIONS

The placement of an IO line is indicated when vascular access is rapidly required for the resuscitation of a patient and standard vascular access is unobtainable or delayed.^{57,58} This includes neonates, infants, children, adolescents, and adults. It may be operationally useful to define a specific time frame or a specified number of peripheral IV attempts before proceeding to IO access. Situations that may require the placement of an IO line are cardiac arrest, extensive burns, sepsis, severe dehydration, shock, status epilepticus, trauma, or any condition that requires urgent administration of fluids, medications, or blood products.^{38,59-64} Current guidelines recommend IO catheterization as the preferred second option if IV access is not quickly obtainable (e.g., 90 seconds or two attempts).⁶⁵⁻⁶⁹

IO access can provide blood samples for typing, crossmatching, and laboratory analysis.⁷⁰ Arterial blood gases, blood urea nitrogen (BUN), calcium, creatinine, electrolytes, and glucose from blood samples obtained through an IO needle are similar to samples taken via traditional routes.⁷⁰⁻⁷³ Values are accurate for bedside point-of-care testing.^{70,73} Laboratory values may be less accurate after 5 or more minutes of active resuscitation, if drugs have been infused through the IO site, or if fluids have been infused through the IO site.⁷¹

CONTRAINDICATIONS

Placement of an IO line is contraindicated in diseased (e.g., osteogenesis imperfecta) or osteoporotic bone. Avoid the placement of an IO line through areas of abscesses, burns, or cellulitis.⁷⁴ Fractures in the ipsilateral bone increase the risk of an extravasation-induced compartment syndrome and nonunion of the fractures.⁷⁵ Failed

placement of an IO line in the same bone is a relative contraindication. Do not use a bone that has had a previous orthopedic procedure, contains hardware, or may contain hardware (i.e., pins, plates, screws, and artificial joints). Do not insert an IO line if the patient is morbidly obese as the needle is too short to enter the medullary cavity or if the patient is so obese that the bony landmarks cannot be palpated. Other contraindications are an actual or possible compartment syndrome or vascular injury in an extremity.

There are contraindications specific to sternal IO access. Do not attempt sternal IO access in patients who weigh less than 50 kg, are small in stature, have a small sternum, have congenital sternal malformations, or have chest wall malformations. Do not consider the blunt trauma patient with a suspected sternal fracture or soft tissue injury over the sternum for sternal IO access. A history of a sternotomy or osteoporosis is a contraindication.

EQUIPMENT

- Sandbag or towels
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution, 1% or 2% lidocaine
- Syringes, 5 to 60 mL
- Primed IV tubing with normal saline
- Tape
- Plastic protective cup
- Leg board for immobilization
- IO access device (Table 70-2)

IO needles are available in numerous sizes and styles (Figure 70-6). **Use only specifically designed IO needles for this procedure.**

Spinal needles often bend and do not penetrate the cortex of the bone. Their long length causes increased resistance to fluid flow. Standard hypodermic needles (e.g., angiocatheters) often bend and do not penetrate the cortex of the bone. Spinal and standard hypodermic needles may break while being inserted and injure the Emergency Physician.

Available models of manually inserted IO devices (Figure 70-6) include the hand-driven threaded-needle SurFast and Cook Intraosseous needle (Cook Critical Care, Bloomington, IN), the Jamshidi bone marrow needle (Baxter Healthcare, Valencia, CA), and the MedSurg Industries Illinois sternal/iliac aspiration needle (MedSurg Industries, Rockville, MD). The typical unit consists of a detachable handle, an IO needle, an obturator, and a sleeve to prevent the needle from penetrating too deeply. The IO needles range in size from 12 to 20 gauge, with the majority used being 15 gauge. The IO needles available today are variations of the basic unit and include adjustable-length shafts to decrease the risk of penetrating too deeply, a variety of tips on the obturator (e.g., lancet, pencil point, and trocar), threaded versus nonthreaded shafts, needle sideports to increase flow rates, numerous lengths, and numerous handle types.

Powered and spring-loaded injection devices have evolved and are widely used. Three currently available devices are the EZ-IO Intraosseous Driver (Vidacare, San Antonio, TX), the Bone Injection Gun (BIG; Wais Medical, Kress USA Corporation), and the NIO (Vidacare, San Antonio, TX). The EZ-IO uses a battery-powered driver to insert the needle to the desired depth (Figure 70-7).²⁰ The BIG incorporates a loaded spring to inject the IO needle, and the desired depth of injection may be adjusted (Figure 70-8).⁷⁶ The BIG and EZ-IO are available in adult and pediatric needle sizes. The NIO is to be used in the humerus and proximal tibia of adults. The devices have numerous advantages when compared to the manual devices. They

are easier to use, are quicker at establishing IO access, require less or no force to insert the IO needle, and do not bend during insertion.

Sternal access devices include the Monoject I-Type Sternal-Iliac Aspiration Needle (Covidien, Mansfield, MA; **Figure 70-9A**) and the First Access for Shock and Trauma (FASTResponder; Pyng Medical, Richmond, British Columbia, Canada; **Figure 70-9B**). The Monoject is a handheld IO device that is rarely used in the Emergency Department. The FASTResponder is a multiple-component kit to be used for sternal IO access in the adult patient. A special introducer limits the depth to which the needle can be inserted. This prevents injury to the underlying great vessels, heart, lung, and mediastinum. This system was evaluated in Special Forces military settings. It was found to be equally useful and safe for IO access.⁷⁶ Sternal IO access devices are used less often than the previously

described powered devices due to possible interference with resuscitation attempts and their occasional incomplete removal, which necessitates surgical intervention.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative if time permits. This procedure is often performed in emergencies. Informed consent can be waived when necessary. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

The primary site of choice for IO line placement is the proximal tibia. Alternate sites include the distal tibia, distal femur, proximal

FIGURE 70-7. The EZ-IO. **A.** The driver, EZ-tubing, EZ-stabilizer, and three lengths of IO needles. **B.** The EZ-stabilizer close up. (Photos courtesy of Vidacare, San Antonio, TX.)

humerus, and the sternum. The proximal humerus allows more central access, while the proximal tibia is often accessible without disrupting airway management and cardiopulmonary resuscitation (CPR).²⁰

Place the patient supine with the lower extremity supported behind the knee with a towel or sandbag. Identify by palpation the landmarks required to perform the procedure. Palpate the bony landmarks with the nondominant hand. The bony landmarks for the proximal tibia are the tibial tuberosity and the flat anteromedial surface of the proximal tibia. The site of IO needle placement is approximately 2 cm below the tuberosity on the flat anteromedial surface of the proximal tibia (**Figure 70-2**). The bony landmark for the distal tibia is the junction of the medial malleolus and the flat anteromedial surface of the distal tibia just posterior to the greater

saphenous vein (**Figure 70-3**).⁷⁴ This is the preferred site in the adult patient. The bony landmarks for the distal femur approach are the medial and lateral condyles of the femur and the patella. Position the IO needle approximately 2 cm above these structures (**Figure 70-4**). This site is used less often in adults because of the abundance of muscle and soft tissue structures but may be an excellent option in infants due to the small size of the tibia. The bony landmark for the humerus is slightly anterior to the lateral midline of the arm at the greater tuberosity with care to avoid the bicipital groove (**Figure 70-5**). The arm should be adducted and internally rotated for optimal positioning.²⁰

Prepare the patient. Clean any dirt and debris from the skin. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry if time permits. **This procedure is painful. The use**

FIGURE 70-8. Spring-loaded IO devices. **A.** The BIG in adult and pediatric sizes. **B.** The NIO. (Photos courtesy of PerSys Medical, Houston, TX.)

of a local anesthetic solution in the conscious or semiconscious patient will reduce the pain associated with IO placement.⁷⁷ Infiltrate local anesthetic solution into the skin, subcutaneous tissues, and periosteum overlying the bone puncture site. Consider infusing 3 to 5 mL of 2% lidocaine (or 0.5 mg/kg in children, to a maximum of 3 to 5 mL) initially and at regular intervals to minimize patient discomfort associated with the IO infusion in the awake patient.¹²

TECHNIQUE

MANUALLY INSERTED IO DEVICES

Examine the IO needle to ensure that it appears to have been manufactured properly. Reidentify the landmarks with the nondominant hand. Stabilize the extremity with the nondominant hand (**Figure 70-10A**). Grasp the IO needle firmly with the dominant hand. The handle of the IO needle should be firmly planted in the palm of the dominant hand. Insert the needle perpendicularly or slightly angulated at a 10° to 15° angle to the long axis of the bone (**Figure 70-10**). **The IO needle should always be directed away from the growth plate to avoid injuring it.** Direct the needle

caudad in the proximal tibial approach and cephalad in the distal tibial and distal femoral approaches.

Advance the IO needle through the skin and subcutaneous tissue until the bone is contacted. Advance the IO needle through the bone. Use a twisting or rotary motion with the simultaneous application of downward pressure to cut through the cortex of the bone (**Figure 70-10A**). **A significant reduction in the resistance to forward motion will be encountered when the cortex is penetrated and the needle enters the medullary canal.** This distance is rarely greater than 1 cm in most patients. An index finger may be placed 1 cm from the bevel of the IO needle prior to advancement. This will help prevent overpenetration into and through the cortex on the opposite side of the bone.⁷⁸ Alternatively, adjust the sleeve so that only 1 cm of the IO needle is exposed. **Stop advancing the IO needle when it enters the medullary canal.**

Remove the stylet when the medullary canal is entered (**Figure 70-10B**). Attach a 5 or 10 mL syringe onto the hub of the IO needle (**Figure 70-10C**). Aspirate blood from the medullary canal to confirm proper placement of the IO needle. Any samples obtained may be sent to the laboratory for subsequent analysis. The aspiration of more than 2 to 3 mL of blood may not be possible in cardiac arrest situations. Attach IV tubing to the hub of the IO needle and begin the infusion of fluids. Medications can be administered through the injection port of the IV tubing. Place a sterile dressing around the skin puncture site and apply pressure for 5 minutes.⁷⁹

IO ACCESS USING THE EZ-IO

The EZ-IO is a reusable, nonsterile, battery-powered driver that uses sterile, disposable, single patient use IO needles. The IO needles are available in three lengths (i.e., 15, 25, and 45 mm) that are all 15 gauge (**Figure 70-7A**). Choose the proper IO needle for the patient, their age, their body habitus, and the insertion site. Use a 45 mm needle in obese patients.⁸⁰ Assess the tissue depth by palpation. Choose an IO needle so that at least one black line on the IO needle shaft will be visible above the patient's skin when the tip is against the bone. The IO needle tip is designed to cut the bone and create a hole the same size as the needle.

Identify the IO insertion site and prepare for the procedure. Clean and prep the skin at the site and surrounding area. **The procedure requires aseptic technique.** Select the appropriate size IO needle. Open the cover of the case that holds the sterile IO needle. Insert the bit on the EZ-IO driver into the base of the IO needle (**Figure 70-11A**). **Leave the cap on the IO needle until it is ready to be inserted.** Open the EZ-Connect tubing and flush it with a syringe containing 10 mL of sterile normal saline. Leave the syringe attached to the tubing after it is flushed.

Reidentify the landmark for the insertion site. Inject local anesthetic solution subcutaneously and down to the periosteum. Remove the cap from the IO needle. Insert the IO needle perpendicular or at a 90° angle to the skin (**Figure 70-11B**). Advance the IO needle through the skin and subcutaneous tissues until the tip is against bone. **At least one black line on the needle shaft should be visible above the patient's skin.** Withdraw the needle and replace it with a longer IO needle if a black line is not visible on the needle shaft. Press the trigger to start the driver shaft and IO needle rotating. **Apply gentle and minimal downward pressure to advance the IO needle into the medullary canal. Stop advancing the driver when a loss of resistance is felt.**

Grasp and firmly hold the hub of the IO needle. Remove the driver (**Figure 70-11C**). **Do not allow the IO needle to move while removing the driver.** Twist the stylet counterclockwise and remove

FIGURE 70-10. Placement of an IO line. **A.** The nondominant hand is used to support the extremity. The IO needle is inserted with a twisting motion to cut through the cortex of the bone. **B.** The handle and obturator are removed. **C.** A syringe is attached to the hub of the IO needle and bone marrow is aspirated.

it while securely holding the IO needle hub (Figure 70-11D). Attach the EZ-IO stabilizer (Figures 70-7B and 70-11E) followed by the primed EZ-Connect tubing. Aspirate bone marrow to confirm proper needle position. **Do not attach a syringe directly to the IO needle hub.** A syringe attached to the hub can result in a fracture of the hub. **Always attach the EZ-Connect tubing and then aspirate and inject through it and not directly through the IO needle hub.** Begin using the IO access.

IO ACCESS USING THE BIG

The BIG is an automatic, spring-loaded device that does not require a power source. It is available in two sizes: adult and pediatric. The insertion site is different for adults and children. Always start at the tibial tuberosity as the initial landmark. For adults, move 2 cm medially toward the inner leg and then 1 cm proximally toward the patient's head. For children, move 1 to 2 cm medially toward the inner leg and then 1 to 2 cm distally toward the patient's foot. Mark this final location as the insertion site. It may also be inserted in the proximal humerus in the adult patient.

Prepare for the procedure. **This procedure requires aseptic technique.** Clean and prep the skin at the insertion site and surrounding area. Open the package and remove the sterile BIG. Rotate the base of the unit to adjust the IO needle penetration depth to the pediatric patient's age: 0 to 3 years at 0.5 to 1.0 cm, 3 to 6 years at 1.0 to 1.5 cm, and 6 to 12 years at 1.5 cm (Figure 70-12A). Use the adult BIG for patients over the age of 12 years. Reidentify the landmark for the insertion site. Inject local anesthetic solution subcutaneously and down to the periosteum.

Position the BIG at the insertion site with the base perpendicular or at 90° to the skin (Figure 70-12B). Firmly grasp the BIG with the nondominant hand. Squeeze and pull out the red safety latch while firmly holding the BIG against the insertion site (Figure 70-12C). **Do not discard the safety latch because it will be used later to**

secure the IO needle. Grasp the upper part of the BIG with the dominant hand (Figure 70-12D). Place two fingers under the wings and the palm on the top of the BIG (Figure 70-12D). Continue to firmly hold the base against the patient's skin with the nondominant hand.

Insert the IO needle. Trigger the BIG by gently pressing down with the palm. The device will eject the spring-loaded IO needle into the bone. **The IO needle should be standing upright firmly in the bone and be stable.** If not, it has been placed into muscle or soft tissue. Gently lift and remove the BIG device without catching on the IO needle hub (Figure 70-12E). Attach the safety latch onto the cannula between the patient's skin and the IO cannula hub (Figure 70-12F). Secure the safety latch to the skin with tape (Figure 70-12F). Gently remove the stylet-trocar, leaving the cannula in place (Figure 70-12G). **If the stylet-trocar is "stuck" and not easily removable, do not pull or try to forcefully remove it.** The IO needle did not penetrate all the way into the medullary cavity and is embedded in the cortex. Insert the square end of the safety latch into the hub of the IO needle and gently twist to remove the IO needle. Repeat the procedure at another site. Gently attach a 5 or 10 mL syringe onto the IO cannula hub without advancing or withdrawing the cannula. Aspirate bone marrow to confirm proper placement (Figure 70-12H). Remove the syringe while holding the hub of the cannula. Attach the IV tubing onto the hub of the cannula (Figure 70-12H). Aspirate bone marrow to confirm proper placement (Figure 70-12H). Flush the IV tubing and cannula with 5 to 10 mL of sterile saline. Begin using the IO access.

INSERTION OF THE NIO

The NIO is automatic and single use (Figure 70-8B). It is spring loaded with a double safety mechanism to maximize caregiver and patient safety. The needle stabilizer fixates the needle firmly.

FIGURE 70-11. Using the EZ-IO. **A.** An IO needle has been applied onto the driver. **B.** Insert the IO needle at a 90° angle to the skin. **C.** The driver has been removed. **D.** The styler is being removed. **E.** The EZ-stabilizer and tubing have been applied.

The device is for use in adult patients and not children. The recommended penetration depth is 2.5 cm. The primary site is the proximal tibia approximately 2 cm medially and 1 cm proximally to the tibial tuberosity. The humerus is an additional site. Adduct the patient's hand and locate the greater tubercle.

Open the pack and take out the NIO (**Figure 70-13A**). Make sure that the NIO is free of all packaging parts. Choose the site for injection. Clean and prepare the skin. **This procedure requires aseptic technique.** Place the nondominant hand on the textured dots on the

lower part of the NIO (**Figure 70-13B**). Position the NIO at 90° to the skin at the injection site (**Figure 70-13B**). Keep the nondominant hand at this position. Unlock the NIO. Rotate the cap 90° in either direction (**Figure 70-13C**). Place the palm of the dominant hand over the cap. Place the fingers of the dominant hand under the wings of the NIO. Press the device against the patient's skin and maintain downward pressure. Pull the trigger wings upward while pressing down on the device to activate the device (**Figure 70-13D**). Firmly hold the base of the needle stabilizer against the insertion site.

FIGURE 70-12 (continued)

Gently pull the NIO up in a rotary motion (**Figure 70-13E**). Hold the needle stabilizer and cannula in place. Remove the stylet by pulling it up in a twisting motion. The keyhole notch on the distal end of the NIO can be used to assist in removing the stylet (**Figure 70-13F**). Attach a 10 mL syringe to the hub of the IO needle. Aspirate bone marrow to confirm the needle is within the medullary canal. Hold the hub of the IO needle and remove the syringe. Attach the IV tubing and begin the infusion (**Figure 70-13G**).

The company recommends the NIO Fixation sticker to affix the NIO stabilizer (**Figure 70-13G**). Cover the insertion site with

a sterile occlusive dressing. Immobilize the patient's arm if the humeral head was used to prevent accidental removal of the device.

INSERTION OF THE FASTResponder

The FASTResponder is single-use device that is easy to insert (**Figure 70-14A**). **The device is for use in patients age 12 and older and not children.** The primary and only site is the sternum. The depth control prevents overpenetration through the back of the sternum and into the mediastinum. The FASTResponder

FIGURE 70-13. Using the NIO. **A.** The NIO is removed from the package. **B.** The NIO is grasped and held over the insertion site. **C.** The cap is turned 90° in either direction. **D.** The unit is compressed. **E.** The NIO is removed. **F.** The stylet is removed. **G.** The IV tubing is attached.

can be inserted and used with CPR due to its location on the manubrium of the sternum. The infusion tubing is mounted on the stylet inside the introducer. It is designed to flex with skin movement. The needles on the introducer do not enter the sternum.

Clean and prepare the skin over the upper sternum. **This procedure requires aseptic technique.** Stand above the patient's head. Open the pack and take out the FASTResponder (**Figure 70-14B**). Remove the locking pin and adhesive liner covering the target foot of the FASTResponder (**Figure 70-14C**). Align the notch on the target foot with the patient's sternal notch with the device at a 90° angle to the manubrium (**Figure 70-14D**). Briefly pause CPR if this is occurring. Push down forcefully on the device to insert the infusion tube (**Figure 70-14E**). Downward pressure pushes the infusion tube through the sternal cortex and into the marrow cavity. Firmly hold the target foot against the

sternum. Pull the device upward leaving only the target foot and infusion tube (**Figure 70-14F**). Remove the anti-buckle support from the infusion tube. Connect the IV tubing to the Luer lock of the infusion tubing (**Figure 70-14G**). Attach the strain-relief hook of the infusion tubing to the target foot (**Figure 70-14H**).

The following are optional steps. Aspirate to confirm the proper location. Remove the protected cover and attach the protective dome.

ASSESSMENT

Assess whether the IO needle is correctly positioned within the medullary cavity. First aspirate blood from the marrow cavity. This may not be possible because of poor circulation in patients with

a cardiac arrest. A second sign of correct placement is to assess whether the IO needle will stand erect without support. Finally, flush the IO line. The ability of the fluid to flow without inducing soft tissue swelling can also be used to confirm proper placement. Ultrasonic visualization of flow within the medullary cavity using color flow Doppler can confirm correct placement, although physical examination as described above may be the most reliable method.⁸¹⁻⁸³ Alternatively, a C-arm fluoroscopic imaging device may be used at the bedside to confirm accurate placement of the IO needle.⁸⁴ **A reassessment must be performed at regular intervals**

to ensure that extravasation does not occur. Circumferential pressures of the involved extremity may be used for serial examination.⁸⁵

AFTERCARE

Secure the IO needle. Secure the manually inserted IO needle by taping it in place. It may be easier to apply 4×4 gauze squares on two sides of the IO needle to support it and then tape the needle and gauze in place. Secure the EZ-IO and NIO needle in the same manner or use the EZ-stabilizer. Tape the safety latch of the BIG to the

FIGURE 70-14 (continued)

skin to secure it. Tape the IV tubing securely at several points. This will prevent traction on the tubing from pulling the IO needle out of the bone. Tape a plastic cup over the IO needle to avoid inadvertent disruption during patient resuscitation or positioning. Immobilize the extremity, if necessary, to help secure the IO line.

Remove the IO line once the resuscitation is complete and another form of secure vascular access has been obtained. Manually inserted IO devices can be removed by gently twisting them and pulling them straight out. **Do not rock the device.** To remove the EZ-IO, attach a 5 or 10 mL Luer lock syringe onto the IO needle hub. Rotate the syringe clockwise and pull it straight out. It may take several rotations of the syringe before the IO needle can be removed. **Do not rock the IO needle or syringe.** To remove the BIG cannula, insert the square end of the safety latch into the hub of the cannula and gently twist and pull to remove it. Remove the cannula and needle stabilizer of the NIO by twisting and pulling vertically. Remove the protective dome, if used, of the FASTResponder. Grasp the infusion tubing as close to the patient as possible with fingers or a clamp. **Pull the infusion tubing in a continuous motion until removed. Do not start and stop the pulling.** The infusion tube will slightly stretch when it is pulled. By twisting and pulling vertically, peel off the target foot. Bleeding at the insertion site can be controlled with a sterile pressure dressing followed by cleansing the skin and a simple bandage. Cover the insertion site with a sterile occlusive wound dressing.

What if advanced imaging (i.e., CT scans and magnetic resonance imaging [MRI] scans) is needed? Metal needles are problematic. They will produce an artifact if scanning the area of the IO. The metal IO is a contraindication to the use of MRI. Obtain a CT scan or delay the MRI scan until alternate access is obtained.

COMPLICATIONS

The most common complications of IO infusions are subcutaneous and subperiosteal extravasation of fluid.^{5,86,87} Under ideal circumstances, the type of IO needle used should not affect extravasation rates.^{88,89} Extravasation is usually due to under- or overpenetration of the cortex. There have been cases of tibial fracture due to overpenetration of the cortex, although this is extremely rare.^{9,90-92} A compartment syndrome may occur when there is extravasation or when IO lines are placed in fractured bones.^{93,94} Necrosis and sloughing of the skin at the insertion site of the IO needle are due to extravasation of fluid or medication.^{88,94} Local hematomas can occur from penetrating muscle, superficial vessels, and the bones. Friction burns and abrasions can be avoided with proper training.⁹⁵

Localized infections may occur after IO needle placement. Cellulitis or the formation of subcutaneous abscesses occurs in 0.7% of patients.⁷⁴ Osteomyelitis has been reported in less than 1% of patients

with IO needles.⁹⁶ Risk of osteomyelitis increases with prolonged IO use, administration of hypertonic fluids, and bacteremia.⁹⁶

Injury to the growth plate is a commonly mentioned complication. The literature does not support this.^{97,98} The rate of the IO infusion and the osmolarity of the infused fluid did not adversely affect the bone marrow or bone development in animal studies.⁹⁹ Air or fat embolism has been mentioned as a possible complication, although there exists no evidence that this is clinically significant.¹⁰⁰⁻¹⁰² Consider a fat embolism if the patient becomes hypoxic or experiences respiratory difficulty shortly after beginning an IO fluid infusion or bolus.

The flow rate of fluid through an IO line may be slower than that through a peripheral IV line depending on the site, gauge of the IO needle, and gauge of the peripheral IV. This may be due to a small marrow cavity, a fibrous marrow cavity, and/or the replacement of red marrow with yellow marrow. Fluid flow rates can be significantly increased by applying a pressure bag onto the IV fluid bag or using a level 1 infuser.¹⁰³ The placement of a second IO line may be required to further increase the amount of fluid that can be infused.

The complications specific to the EZ-IO include hub fracture after insertion and separation of the needle from the hub upon removal. Too much downward pressure upon IO needle insertion can result in it penetrating the back of the bone. The other general complications are described above.

The complications associated with the BIG or NIO are primarily from incorrect use. **Never remove the safety latch until the BIG is against the patient's skin over the insertion site.** Removal of the safety latch activates the device. The IO needle can be forcefully ejected and injure the patient or a health care provider if the BIG or NIO is squeezed after the safety latch is removed. **Never place a finger over the distal end. Always grasp the devices properly. Grasping it upside down can result in the IO needle penetrating the Emergency Physician's hand.** Incorrectly adjusting the penetration depth can result in the IO needle penetrating the back of the bone. The other general complications are described above.

There are complications associated with the FASTResponder. These are usually device related and minor. Flush the line if the infusion is slow or not flowing. If this does not resolve the flow problem, discontinue use of the sternal IO and try an alternative method. Extravasation at the insertion site should be minimal if at all. Significant extravasation requires the discontinuation of the sternal IO and an alternative method. Do not use the sternal IO if the infusion tubing is not secure. The company claims a 1 in 1,000,000 rate of sternal overpenetration.

SUMMARY

The placement of an IO line is an excellent option in the resuscitation of a patient when traditional vascular access techniques have failed. The procedure is technically straightforward and has been demonstrated to be successful in the hands of trained health care workers, including prehospital personnel. Complications have been related mostly to technical mistakes and can be avoided if care is taken to correctly identify landmarks, avoid the growth plate, regulate the depth of IO needle placement, and ensure early removal of the IO line.

Umbilical Vessel Catheterization

Jeanne Noble

INTRODUCTION

Umbilical vessel catheterization was first described by Diamond in 1947 for an exchange transfusion in a neonate.¹ Umbilical vessel catheterization serves many important functions in the ill neonate and is a reliable method of obtaining rapid vascular access.² Umbilical vessel catheters may be used for fluid resuscitation, blood transfusion, medication administration, frequent blood sampling, and cardiovascular monitoring.²⁻⁶ **The use of these catheters carries risk of morbidity and mortality.** Either the umbilical artery or vein may be used for vascular access. The umbilical arteries begin to constrict immediately after birth and can typically be cannulated during the first few days of life. The umbilical vein can be accessed up to 7 to 10 days after birth (i.e., when the umbilical stump dries up).⁷

Umbilical artery catheterization is more desirable than umbilical vein catheterization. The umbilical artery allows frequent arterial

blood gas sampling and continuous blood pressure monitoring and administration of substances (e.g., blood products, fluids, and medications). **Umbilical artery catheterization is more difficult and time consuming to perform. Umbilical vein catheterization is the preferred procedure for the infant in shock and in need of rapid resuscitation.** Arterial access can be obtained later in the controlled environment of the Neonatal Intensive Care Unit (NICU). **Umbilical vessel catheterization can lead to serious complications and should be reserved for the patient in whom intraosseous or peripheral venous access cannot be rapidly secured.**^{6,8}

ANATOMY AND PATHOPHYSIOLOGY

The fetal circulatory system differs from that of the neonate (**Figure 71-1**).⁷ Oxygenated blood from the placenta travels via the umbilical vein, through the ductus venosus in the liver, to the inferior vena cava (IVC), and into the right atrium. Oxygenated blood from the IVC preferentially enters the left atrium through the foramen ovale. It then enters the left ventricle followed by the aorta. This oxygen-rich blood supplies the brain prior to mixing with the oxygen-poor blood coming through the

FIGURE 71-1. The fetal circulation.

FIGURE 71-2. Anatomy of the umbilical cord.

ductus arteriosus. Deoxygenated blood from the superior vena cava (SVC) enters the right ventricle and is pumped to the pulmonary artery. It then passes through the ductus arteriosus to meet the oxygenated blood in the aorta.

Pulmonary vascular resistance decreases dramatically as the infant takes its first breath. The systemic vascular resistance increases when the umbilical cord is clamped. These changes in resistance cause the foramen ovale to close. The ductus arteriosus closes within 24 to 48 hours due to the release of prostaglandins and increased blood oxygen tension. The ductus venosus closes when the umbilical cord is clamped.

The umbilical vein and arteries can be easily differentiated by examination of a cross section of the umbilical cord (**Figure 71-2**). The umbilical vein is a single thin-walled vessel with a large lumen. It is usually flattened in one direction. There are two thick-walled umbilical arteries that are significantly smaller in diameter than the umbilical vein. Occasionally, only a single umbilical artery is present. Some describe the umbilical cord as a “happy face” with the two arteries as the eyes and the vein as the mouth.

INDICATIONS

Umbilical artery catheterization is indicated when frequent arterial blood gas determinations and continuous monitoring of blood pressure are required in the first few days of life.⁵ An umbilical artery catheter (UAC) can be used for delivering blood, fluids, total parenteral nutrition, medications, and exchange transfusions.^{3,4} It reduces the need for multiple venipunctures and heel prick capillary blood sampling in the critically ill neonate.⁹ Neonates under 24 hours of age can usually be catheterized without much difficulty. A skilled Emergency Physician can sometimes perform this in neonates up to 7 days of age.³

Umbilical vein catheterization is easier to perform than umbilical artery catheterization. It is the preferred procedure for the neonate in shock needing rapid administration of intravenous fluids, blood, or medications.¹ The umbilical vein can be used to monitor central venous pressure and to perform invasive cardiac procedures.¹⁰ The vein may be cannulated in neonates up to 10 days after birth.

CONTRAINDICATIONS

Umbilical vessel catheterization in the Emergency Department should be performed on severely ill neonates in whom intraosseous and peripheral vascular access is unlikely to be successful. The contraindications are similar for umbilical vein and umbilical artery catheterization. These include the presence of a gastroschisis, omphalocele, omphalitis, and peritonitis.^{3,11} **Never insert an umbilical catheter if there are any signs of infection on or around the remnant of the umbilical cord.** Umbilical vessel catheterization is contraindicated if a neonate is older than 1 to 2 weeks of age.

An alternate route of vascular access is required if the possibility of an abdominal abnormality exists, as manifested by a distended abdomen or visible defects.³ Relative contraindications for placement of a UAC include decreased perfusion to the lower extremities, decreased perfusion to the buttocks, or suspicion of necrotizing enterocolitis.

EQUIPMENT

- Umbilical vein catheter, 5.0 French or 3.5 French
- Umbilical artery catheter, 5.0 French or 3.5 French
- Umbilical tape
- Povidone iodine or chlorhexidine solution
- Sterile gauze
- Adhesive tape
- Silk suture, 3–0 or 4–0
- Suture kit
- Smooth-curved iris forceps
- 2 small, smooth-curved hemostats
- #10 or #11 scalpel
- 3-way stopcock
- 10 mL syringe filled with normal saline
- Sterile drape
- Sterile gown and gloves
- Cap and face mask
- Radiant infant warmer
- Cardiac monitor
- Pulse oximeter

UACs and umbilical vein catheters (UVCs) are available in a variety of sizes. UVCs are available as single-lumen or double-lumen catheters. Catheters with side holes are only used for exchange transfusions. Use a 5.0 French umbilical catheter in neonates weighing more than 1500 gm and a 3.5 French catheter in neonates weighing less than 1500 gm.⁷

Umbilical vessel catheterization kits are commercially available from several manufacturers (**Figure 71-3**). The kits are sterile, disposable, and intended for single patient use. They contain all the equipment required for catheter insertion but do not always include the actual catheter. It is important to be familiar with the hospital's kit prior to use.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the parent and/or the patient's caregiver. Obtain an informed consent for the procedure and place this in the medical record. Give parents the option to leave the room or look away as the procedure can be disconcerting to some.

Umbilical vessel catheterization should be performed in the sick neonate when intraosseous and peripheral venous access is unlikely to be rapidly secured. All equipment should be readily available on a preprepared sterile tray. Place the tray with the instruments on a Mayo stand next to the neonate's bed. Place the neonate under a radiant warmer with a light source. Place the neonate on a cardiac monitor, continuous pulse oximeter, and supplemental oxygenation if needed. Place the neonate supine with the lower extremities in the frog-leg position (**Figure 71-4**). Place their arms and legs in soft restraints to prevent contamination of the sterile field (**Figure 71-4**).

A

B

C

FIGURE 71-3. Some of the commercially available kits for umbilical vessel catheterization.

This procedure requires strict sterile technique. The Emergency Physician performing the procedure should wear a cap, mask, sterile gloves, and sterile gown. Scrub the umbilical cord, umbilical cord clamp, and the neonate's abdomen with povidone iodine or chlorhexidine solution and allow it to dry. Place sterile drapes to form a sterile field around the umbilical area. **Ensure the neonate's head is exposed for observation.**

TECHNIQUES

PREPARATION OF THE UMBILICAL CORD

Sterile technique must be maintained throughout the entire procedure. Loosely tie a piece of umbilical tape around the base of the umbilical cord (**Figure 71-5**). A thin gauze packing strip can be used if umbilical tape is unavailable. Place purse-string sutures

FIGURE 71-4. Positioning of the neonate.

with 3-0 or 4-0 silk in small bites around the base of the umbilical cord and just above the umbilical tape (**Figure 71-5**). **Avoid piercing the umbilical vessels or the skin of the abdominal wall.** Leave the suture untied and the ends uncut. This will be used later to secure the catheter. Gently grasp the umbilical cord. Use a #10 or #11 scalpel blade to cut the umbilical cord to expose a smooth, clean surface of the umbilical cord (**Figure 71-5**). **Do not cut the cord too close to the base in case it needs to be recut for a repeat attempt.** Tighten the umbilical tape if blood is oozing from the cut umbilical cord. **Blot the blood with gauze squares. Do not rub the gauze against the cord to prevent damaging the fragile umbilical cord.** Grasp the umbilical cord with forceps or fingers

FIGURE 71-5. Preparing the umbilical cord stump. Umbilical tape has been placed at the base and tied loosely. A purse-string suture has been placed through the stump and just above the umbilical tape. The distal end of the umbilical cord is removed along the dotted line.

and identify the three vessels (i.e., two arteries and one vein). The arteries are smaller and round and have thick muscular walls. The vein is larger, has a thinner wall, and is less round than the arteries. The umbilical artery or vein may now be catheterized as described in the following sections.

UMBILICAL ARTERY CATHETERIZATION

Determine the desired position of the catheter tip (**Figure 71-6**). UACs have been placed in either a “high” or “low” position. The high position is associated with a lower occurrence of vascular complications, removal, and adverse sequelae.^{5,6,12} It is the technique described here. **The catheter tip is placed between the sixth and tenth thoracic vertebrae.** This level corresponds to just above the diaphragm, between the ductus arteriosus and the origins of the mesenteric arteries.^{3,13-15}

A variety of methods have been used to determine the insertional length of UACs.¹⁶⁻¹⁹ Some of these include electrocardiographic changes during placement, echocardiography-guided insertion, and ultrasound-guided insertion.²⁰⁻²⁴ These methods are hard to perform in clinical practice. Other methods for determining the appropriate depth of catheter insertion are the shoulder-to-umbilicus length and the neonate’s birth weight referring to standardized graphs.¹⁹

Many centers use a calculation derived by Dunn on postmortem infants. The length of insertion to the high position is measured from the external shoulder to the umbilicus (**Figure 71-4**).²⁵ Measure the shoulder to umbilicus length by measuring the distance between the tip of the shoulder to the level perpendicular to the umbilicus (**Figure 71-4**). The catheter length to be inserted is

FIGURE 71-6. Positioning of the tip of the umbilical artery catheter. The low position is just above the aortic bifurcation between L3 and L5. The high position is above the diaphragm, between the ductus arteriosus and the mesenteric arteries and between T6 and T10. The shaded box represents the vertebral bodies in the midline.

FIGURE 71-7. Graph to determine the correct length of catheter to insert into the umbilical artery. Using the shoulder-umbilical length and the desired position of the catheter tip, determine the length of catheter on the y-axis to be inserted into the artery. Add the length of the umbilical stump to the umbilical artery catheter length found on the y-axis of the graph to determine the corrected length of catheter to be inserted. (Adapted and modified from reference 13.)

determined using a nomogram using the shoulder-umbilical length plus the length of the umbilical stump (**Figure 71-7**). Three curves are available corresponding to the desired position of the UAC tip. The Dunn method always requires use of a standardized graph and may be impractical in emergency situations.

The Wright equation has been shown to provide more accurate estimations of catheter insertion length in both full-term and low-birth-weight neonates.^{26,27} It does not require the use of a graph. This formula is UAC insertion length (cm) = $4 \times \text{birth weight (kg)} + 7$ + the length of the umbilical stump (cm).

Fill the catheter with normal saline. Attach a three-way stopcock in the closed position to the hub of the catheter. Identify the arteries and choose one for catheterization. Grasp the distal portion of the umbilical cord with the two smooth-curved hemostats to stabilize the end of the umbilical cord (**Figure 71-8**). Instruct an assistant to hold the hemostats. **Do not apply traction to the hemostats to**

FIGURE 71-8. Preparation for catheter insertion. The upper edges of the umbilical cord stump are stabilized with two smooth-jaw curved hemostats. A smooth-jaw curved iris forceps is placed into one umbilical artery and allowed to open and dilate the artery.

FIGURE 71-9. A new and novel technique for UAC placement. **A.** Insert suture needle directly into the umbilical artery lumen. **B.** Drive the needle through arterial sidewall and Wharton's jelly. **C.** Apply gentle upward traction to the suture. **D.** Insertion of umbilical catheter.

prevent injury to the umbilical cord. Insert the tips of the smooth-curved iris forceps approximately 0.5 cm into the lumen of the artery and gently allow the jaws of the forceps to open (**Figure 71-8**). This will dilate the arterial lumen. Repeatedly insert and open the tips of the curved iris forceps within the arterial lumen to a depth of 0.5 to 1.0 cm.³ **Inadequate dilation is the most common cause of failure to catheterize the umbilical artery.**

A novel alternative technique has been developed.²³ Access the umbilical artery by inserting a 4–0 or 5–0 silk suture needle directly into the arterial lumen and out the sidewall of the umbilical stump approximately 3 to 4 mm below the opening of the arterial lumen (**Figures 71-9A and 71-9B**). Apply gentle upward traction to the suture (**Figure 71-9C**). This opens and stabilizes the lumen of the artery. Dilation of the lumen with iris forceps may be performed, if needed, as described above.

Grasp the umbilical catheter approximately 1.0 cm from the tip. Gently insert the tip of the catheter into the artery (**Figures 71-9D and 71-10**). Apply gentle pressure for about 30 seconds. The muscles

of the artery may spasm and prevent the catheter from advancing. Remove the catheter if the spasm persists. Place 0.1 mL of a 2% lidocaine solution into the catheter tip.³ Reinsert the catheter and flush the lidocaine into the artery at the level of the spasm. A gentle twisting motion may allow the catheter to advance if it still will not advance. Catheterize the other umbilical artery if this fails. Advance the catheter to the predetermined length. Increased resistance will be felt as the catheter goes through the base of the umbilical cord and navigates the curve of the umbilical artery into the femoral artery. Tighten the umbilical tape to temporarily secure the catheter.

Obtain fluoroscopic, plain radiographic, or ultrasonic confirmation of placement prior to using the catheter. The catheter may pass into the aorta but then curve distally into the iliac or femoral artery. This can result in blanching, cyanosis, or necrosis of the lower extremity and/or the buttocks.^{27,28} This occurs more frequently when a 3.5 French catheter is inserted in a large neonate. The larger 5 French catheter will usually advance cephalad in the aorta. The distally advanced catheter can be partially withdrawn, twisted 90°, and readvanced using real-time fluoroscopy or ultrasound. **Catheters provoking lower extremity cyanosis, blanching, or decreased distal perfusion must be removed even if placed correctly. Never advance a catheter that has been previously placed as it can introduce an infection.**

UMBILICAL VEIN CATHETERIZATION

Catheterizing the umbilical vein is much easier than the umbilical artery. The lumen is larger and easier to negotiate. This quality makes the umbilical vein more desirable for vascular access in emergency situations.^{8,29}

It is acceptable to simply insert the UVC approximately 4 cm until blood is aspirated then advance the catheter an additional 1 to 2 cm during a resuscitation of the critically ill neonate. The desired position of the UVC tip can be more carefully determined in less emergent situations. It should be ideally located just beyond the ductus venosus at the junction of the IVC and the right atrium (**Figure 71-11**). Measure the shoulder-umbilical length (**Figure 71-4**). Determine the umbilical catheter length to be inserted into the vein using the shoulder-umbilical length and the desired position of the catheter tip (**Figure 71-12**). Add the length of the umbilical stump to the umbilical vein catheter length found on the y-axis of the graph to determine the corrected length of catheter to be inserted. Another method to calculate the depth of insertion is $\text{length (cm)} = \{[(3 \times \text{body weight [kg]}) + 9] \div 2\} + 1 \text{ cm}$.

Umbilical vein catheterization is like that of the artery with a few exceptions. Any visible clot should be removed from the vein prior to inserting a UVC. No dilation of the vein is required. **An emergency UVC is rapidly inserted 1 cm beyond where blood is first**

FIGURE 71-10. The catheter is inserted into the umbilical artery and advanced to the desired depth.

FIGURE 71-11. Positioning of the tip of the umbilical vein catheter. The tip should be above the diaphragm, at the junction of the inferior vena cava and the right atrium.

aspirated (i.e., approximately 5 cm beyond the umbilical stump) and may be used without waiting for radiographic confirmation of placement. It is imperative that the catheter not be inserted too deeply to prevent entry into the hepatic vessels via the ductus venosus as medications could potentially cause hepatocellular damage.^{3,6,8,30,31} The catheter can be replaced with a more permanent line once the patient has been stabilized.²⁹ Place the nonemergent UVC with the tip above the diaphragm, at the junction of the

FIGURE 71-12. Graph to determine the correct length of catheter to insert into the umbilical vein. Using the shoulder-umbilical length and the desired position of the catheter tip, determine the length of catheter on the y-axis to be inserted into the vein. Add the length of the umbilical stump to the umbilical vein catheter length found on the y-axis of the graph to determine the corrected length of catheter to be inserted. (Adapted and modified from reference 13.)

IVC and right atrium as determined previously. Tighten the umbilical tape to temporarily secure the catheter. Obtain fluoroscopic, plain radiographic, or ultrasonic confirmation of placement prior to using the catheter.²³

UMBILICAL MULTIPLE-LUMEN CATHETERS

Reliable vascular access can be problematic in the sick neonate.³² Insertion of a double-lumen or triple-lumen catheter into the umbilical vein can provide additional venous access for the administration of incompatible drugs (e.g., vasopressor agents, calcium solutions, or sodium bicarbonate solutions).^{33,34} It is also useful for drugs requiring continuous infusions and leaves other ports for blood sampling, central venous pressure measurements, maintenance fluids, or medication administration.³⁴ Infuse all of these solutions into the proximal lumen(s) and allow measurements of central venous pressures from the distal port. Multilumen catheters can be placed directly by the same methods as a single-lumen catheter or using the Seldinger technique as with inserting a central venous line (Chapter 63). **The increased pliability of the multilumen catheter makes passage into the hepatic veins more likely.**

A wire exchange technique may be used to place a multiple-lumen catheter in neonates with an indwelling single-lumen catheter. This method decreases the probability of loss of vascular access during the exchange. It has the risk of the guidewire entering the heart and causing a cardiac dysrhythmia and/or myocardial perforation. This technique should only be performed by those familiar with the Seldinger technique in replacing an umbilical catheter.

The catheter exchange over a guidewire requires strict sterile technique. Insert a guidewire through the umbilical catheter. Firmly hold the guidewire. Withdraw the catheter over the guidewire. **Never let go of the guidewire which must always remain within the vein.** Advance the multilumen catheter over the guidewire and into the vein while securely holding the guidewire. Continue to advance the multilumen catheter to its predetermined length. Remove the guidewire while maintaining the catheter in the umbilical vessel. Tighten the umbilical tape to temporarily secure the catheter. Obtain fluoroscopic, plain radiographic, or ultrasonic confirmation of placement prior to using the catheter.

ASSESSMENT

Confirm the proper placement of the catheter tip (Figure 71-13). The umbilical tape has been tightened to temporarily secure the catheter within the umbilical cord. **Do not infuse anything through the line until proper placement is confirmed in a nonemergent situation.** This can be accomplished with fluoroscopy, plain radiographs, or ultrasonography. If the catheter has been inserted too far, withdraw it and reevaluate the new catheter tip position. **If the catheter has not been inserted far enough, do not advance the catheter. Withdraw the catheter and restart the procedure with a new catheter.**

AFTERCARE

Secure the catheter more permanently after confirming that the catheter tip is in the desired location (Figure 71-14). Tighten and tie a knot in the previously placed purse-string suture. Wrap the loose ends of the suture around the catheter as it enters the umbilical vessel and secure it with several square knots (Figure 71-14). **Loosen and remove the umbilical tape to avoid umbilical cord necrosis.**⁵ Secure the catheter to the abdominal wall with adhesive tape or a large transparent dressing (Figure 71-14). Antibiotic ointment may be applied to the junction of the umbilical cord and the catheter.

B

FIGURE 71-13. Plain radiographs to confirm the placement of an umbilical catheter. **A.** Anteroposterior view. **B.** Lateral view. ETT, endotracheal tube; ECG, electrocardiogram; NGT, nasogastric tube. (Used from <http://wikiradiography.net>.)

COMPLICATIONS

Significant morbidity can be associated with umbilical artery and vein catheterization.³⁵ Prevention of complications requires strict adherence to sterile technique, flushing of the catheter prior to insertion, gentle catheter manipulation during insertion, and accurate positioning of the catheter. It is essential that no air be allowed to enter the catheter. An air bubble can enter the central circulation, pass through the foramen ovale, lodge in an artery, and lead to end-organ damage (e.g., stroke, myocardial infarction, or death).^{36,37}

Complication rates have been reported to be as high as 20% for venous catheters and 10% for arterial catheters.³⁸ A venous catheter placed in the portal system may lead to hepatic necrosis, hemorrhage, portal vein thrombus, portal hypertension, or pulmonary embolism.^{4-6,30} Neonates are at higher risk for thromboembolic

A

B

FIGURE 71-14. Securing the umbilical vessel catheter. **A.** The purse-string suture is tied about the umbilical cord and the umbilical tape is removed. The ends of the suture are wrapped around the catheter, as it enters the umbilical vessel, and secured with square knots. **B.** Tape is applied to secure the catheter to the abdominal wall.

events because of their underdeveloped clotting mechanisms and smaller vessel diameters.³⁵ Phlebitis or nosocomial sepsis can ensue if strict aseptic technique is not followed.³⁸ The catheter can be transected or form a knot intravascularly.^{39,40} Vessel and bowel perforation from forceful manipulation of the catheter, an air embolus from an unflushed catheter, false track formation, cardiac arrhythmias, damage to cardiac valves, and myocardial perforation have all been reported.^{4,8,30,38,41} Necrotizing enterocolitis, biliary venous fistula, pericardial effusion, hypoglycemia from high positioning of a UAC, bladder rupture, congestive heart failure, hypertension, transection of an omphalocele, transection of the catheter, intravascular knots in the catheter, and Wharton's jelly embolus have also been reported.⁴¹⁻⁴⁸ A persistent urachus in the umbilical cord stump may be mistaken for an umbilical vein. Catheterization of the urachus will result in the flow of urine from the catheter. This is easily identified and corrected.

Malpositioning of the UVC has resulted in rare complications such as pneumopericardium, cardiac tamponade, pleural effusion, pulmonary hemorrhage, pulmonary edema, pulmonary infarction, pulmonary abscess, cardiac thrombosis, endocarditis, myocardial perforation, atrial flutter, hyponatremia, perforation of the peritoneum, perforation of a Meckel's diverticulum, perforated urachal remnant, ascites from intraperitoneal extravasation of total parenteral nutrition, esophageal varices, hepatic laceration, hepatic necrosis, hepatic abscess, hepatic calcifications or bladder calcifications with infusion of calcium gluconate, biliary fistula, perforation of the IVC, gastric outlet obstruction, or bladder rupture.^{9,40,49-69}

Malpositioning of the UAC has rarely resulted in sciatic nerve damage, refractory hypoglycemia from infusion into the celiac axis, or spinal cord injury with paraplegia from infusion into the artery of Adamkiewicz.^{3,27,38,70,71} Umbilical artery catheterization may be complicated by an abdominal aortic aneurysm, aortic coarctation, vasospasm, thrombosis, or embolism, causing ischemia of the lower extremities or intraabdominal organs.^{2,6,30,38,72-75}

Vasospasm can occur within moments of catheter insertion or up to several hours following placement. The signs include progressive ischemia resulting in discoloration or mottling of the lower extremities and/or buttocks. Embolization of clots can cause loss of digits, hematuria, kidney failure, hypertension, necrotizing enterocolitis, bowel infarction, cyanosis or blanching of the skin (i.e., of the back, buttocks, or legs), or skin ulceration.

SUMMARY

Umbilical vessel catheterization is a readily available method of obtaining vascular access in the sick newborn. These vessels can be used for fluid resuscitation, blood transfusion, medication administration, frequent blood sampling, and cardiovascular monitoring. Umbilical access is reserved for infants in whom intraosseous and peripheral vascular access is likely to be unsuccessful. Serious complications can result from using the umbilical vessels.

Arterial Puncture and Cannulation

Justin Grisham and Jennifer Stankus

INTRODUCTION

Arterial blood gas sampling is an essential component of the care of many Emergency Department patients. It provides key information regarding a patient's oxygenation and acid-base status. Arterial cannulation allows for continuous and accurate blood pressure monitoring and frequent blood gas sampling in the care of the critically ill

patient. There are many issues associated with obtaining and maintaining arterial access. Placement of an arterial line occurs less commonly than venous access. It is important to know when to obtain arterial access, where to obtain arterial access, and how to obtain arterial access. The use of an arterial line provides a more accurate blood pressure than using a noninvasive cuff.

ANATOMY AND PATHOPHYSIOLOGY

Knowledge of the arterial anatomy is a key factor in the success of arterial puncture and cannulation. It is important to recognize that nerves and veins are in close proximity to the desired arteries in order to avoid complications. The anatomy and positioning for radial, brachial, femoral, and dorsalis pedis artery access are described below.

RADIAL ARTERY

The radial artery is the preferred site for arterial puncture and cannulation. One reason is the comparative ease of identifying the anatomic location of this artery. A second reason is the collateral nature of the arterial blood supply to the hand provided by the radial and ulnar arteries (**Figure 72-1**). The ulnar artery is not often used due to its smaller size. Terminal branches of these two arteries meet in the palm of the hand to form the deep and superficial palmar arterial arches (**Figure 72-1**).

The radial artery is just medial and proximal to the radial styloid process on the ventrolateral wrist (**Figure 72-1**). Dorsiflexing the wrist approximately 45° places the radial artery at its most superficial position to the skin and can aid in palpating the arterial pulse.¹ Another notable landmark is the flexor carpi radialis tendon immediately medial to the radial artery. The recommended point of needle or catheter insertion is at the proximal flexor crease of the wrist and directly above the radial artery pulse.

FIGURE 72-1. Anatomic location of the radial and ulnar arteries. Collateral circulation is provided by the superficial and deep palmar arches.

Perform an Allen test to assess the adequacy of the collateral circulation to the hand prior to radial artery puncture or cannulation (Figure 72-2).²⁻⁴ Ask the patient to repeatedly close their hand tightly into a fist and open it to force blood out of the fingers while manually occluding the radial and ulnar arteries (Figure 72-2A). Continue this process for 1 minute. Ask the patient to open their hand. The fingers will blanch and become pale due to the occlusion of the arterial inflow. Release the finger occluding the radial artery (Figure 72-2B). Measure the time it takes for blushing of the palm to occur. It is considered normal if it is < 7 seconds, equivocal at 8 to 14 seconds, and abnormal if > 14 seconds.² Repeat the test with release of the ulnar artery compression to confirm arterial flow into the hand. **The purpose of an Allen test is to confirm arterial inflow from both the radial and ulnar arteries.**

An alternative method of evaluating the collateral circulation involves the use of a pulse oximeter with a visual pulse waveform display.⁵ This is useful in the unconscious patient, uncooperative patient, or very young patient. Place the pulse oximeter sensor on the patient's thumb. Observe the visual display to confirm a waveform is present. Occlude the radial artery and examine the waveform on the monitor. Either an ulnar dominant system or a radial dominant system with adequate collateral circulation is likely if the waveform remains unchanged during radial artery occlusion.⁵ Occlude the ulnar artery and examine the waveform on the monitor. The ulnar artery can supply the hand if the waveform is unchanged. An ultrasound (US) with Doppler can be used instead of pulse oximetry.⁶

The performance of an Allen test to confirm adequate collateral circulation to the hand is generally advocated before radial

artery puncture or cannulation. There is concern that radial artery occlusion from an intraluminal clot or an external hematoma can result in hand ischemia if the ulnar artery cannot provide adequate collateral blood flow. Some authors have questioned the utility of performing an Allen test.^{2,3,7,8} The Allen test is subjective, often improperly performed, and has poor sensitivity and specificity to predict complications.⁹ The relative safety of radial artery cannulation without the Allen test has been demonstrated in a large case series of patients without major peripheral vascular disease.⁷ **An abnormal Allen test may not preclude radial artery puncture or cannulation but may indicate a greater need for caution and alert the Emergency Physician to potential problems after the procedure.**^{3,6} This can include arterial thrombosis, hand ischemia, and hand necrosis. **It is recommended, but not required, to cannulate another site if the Allen test is abnormal.**

BRACHIAL ARTERY

The brachial artery courses along the medial side of the antecubital fossa just lateral to the median nerve (Figure 72-3). The brachial artery divides at approximately the level of the neck of the radius to become the ulnar and radial arteries. The brachial artery in the antecubital fossa is lateral to the medial epicondyle of the humerus and medial to the biceps brachii muscle. The brachial artery is more easily identified when the elbow is fully extended.

Palpate the medial epicondyle of the humerus. Move laterally until the medial edge of the biceps muscle is palpated. Palpate the brachial artery pulse just medial to the biceps muscle. The arterial pulsation is most easily identified at the level of the proximal flexor crease of the antecubital fossa. The preferred location for puncture or cannulation of the brachial artery is in the antecubital fossa and directly above the brachial artery pulse. Alternatively perform the procedure just proximal to the antecubital fossa. Keep the arm in extension while the cannula is in place. **The brachial artery does**

FIGURE 72-2. The modified Allen test. **A.** The distal radial and ulnar arteries are occluded. **B.** The ulnar artery remains occluded while determining if the radial artery can supply adequate blood flow to the hand.

FIGURE 72-3. Anatomic location of the brachial artery. Note the median nerve running just medial to the artery and the biceps brachii muscle just lateral to the artery.

FIGURE 72-4. Anatomic location of the femoral artery. Note the proximity to the femoral nerve and vein.

not have the same degree of collateral circulation as the radial artery and care should be taken if this site is chosen.

FEMORAL ARTERY

The bony anatomic landmarks used to identify the femoral artery are the anterior superior iliac spine and the tubercle of the pubic symphysis. The artery lies approximately midway between these two points after it courses under the inguinal ligament to enter the thigh (**Figure 72-4**). The femoral nerve and vein run parallel and adjacent to the artery. The vein lies just medial to the artery and the nerve just lateral. The femoral artery is larger than other arteries commonly cannulated and lies significantly deeper than the radial or brachial arteries. This makes it necessary to use a longer cannula and may require a longer needle for a simple arterial puncture to be successful. Extension and slight abduction of the hip maximizes access to the femoral triangle, improves the ability to palpate the artery, and provides a maximal work area for the procedure.

DORSALIS PEDIS ARTERY

The dorsalis pedis artery is a continuation of the anterior tibial artery on the dorsal surface of the foot. Puncture and cannulation of the dorsalis pedis artery constitute a good second choice if the radial artery is unsuccessfully cannulated or unavailable.¹⁰ The pulse is often easily palpable between the first and second metatarsal due to its superficial location. Its distal location does not interfere with other resuscitative efforts and is convenient for the patient. The risk of foot ischemia is minimal due to the abundant collateral circulation to the foot and ankle. There are no significant structures to injure adjacent to the dorsalis pedis artery. This artery may be absent in some people or have significant variability in its anatomic location. It may be difficult to identify the dorsalis pedis pulse in the hypotensive patient.

ALTERNATIVE ARTERIAL SITES

There are several alternative sites that are occasionally used for arterial puncture and cannulation. These include the superficial temporal artery, the axillary artery, and the ulnar artery. The superficial temporal artery is often used in neonates and young infants in the

Intensive Care Unit. Cannulation of this artery is rarely performed in the Emergency Department because of its location and the ability to maintain access.

The axillary artery is a continuation of the subclavian artery after the first rib. The axillary artery crosses the teres major tendon to enter the arm as the brachial artery. The axillary artery can be deep to the skin surface. An advantage of this artery is the ease of locating the palpable pulse, even in the hypotensive patient.^{11,12} An accurate blood pressure devoid of the effects of vasoconstriction can be obtained. US makes it easier to obtain arterial access and increases the success rate.^{11,12}

The disadvantages of cannulating the axillary artery are significant.¹³ The axilla is poorly accessible. The patient's arm must be abducted, externally rotated, and immobilized during and after the procedure. The course of the artery changes with arm position. The artery is contained within the axillary sheath along with the axillary vein and brachial plexus. **There is a significant risk of nerve injury if the needle penetrates the brachial plexus.** The risk of an arterial embolus is higher in central arteries when compared to peripheral arteries.

The ulnar artery and the radial artery are the terminal branches of the brachial artery. The ulnar artery is superficial at the wrist and the pulse is easily palpable. The ulnar artery is significantly smaller in most people when compared to the radial artery. This makes the procedure more technically difficult. An ulnar artery may be absent or extremely small in some patients. The ulnar artery lies adjacent to the ulnar nerve. This increases the possibility of nerve injury if the needle penetrates the ulnar nerve. It can be difficult to identify the artery in the patient with anasarca, obesity, peripheral edema, or peripheral vascular disease.

INDICATIONS

The principal indications for arterial blood sampling include the determination of the acid-base status, blood carbon dioxide (CO_2) content, and blood oxygen (O_2) content.^{14,15} The need for arterial blood gas (ABG) sampling for O_2 determination has decreased substantially with pulse oximetry. Pulse oximetry may poorly reflect true oxygenation in the setting of hypothermia, severe hypotension, or severe hypoxia. Therefore, ABG analysis persists as the true measure of arterial oxygenation.¹⁶ End-tidal CO_2 (E_tCO_2) monitoring has decreased the utilization of ABG samples for CO_2 measurement. E_tCO_2 measurements may grossly underestimate the true CO_2 contents of the blood in patients who have large dead space ventilation or low cardiac output.¹⁷

ABG samples are useful for accurate pH monitoring of patients with obstructive lung disease, other pulmonary disorders, and shock. Possibly the most important indication for ABG sampling in the critically ill patient is the determination of the patient's acid-base status. Venous sampling may occasionally suffice for monitoring the pH (e.g., diabetic ketoacidosis).¹⁸ The measurement of venous blood pH is much less reliable as a surrogate for arterial pH in patients with shock and other critical illnesses.¹⁹ Arterial blood samples are still used for the measurement of carboxyhemoglobin and methemoglobin level. Arterial and venous co-oximetry carboxyhemoglobin values are closely correlated and may be used to screen patients thought to have been exposed to carbon monoxide.²⁰

The three principal indications for arterial catheter placement are the need for continuous monitoring of arterial blood pressure, the need for frequent ABG sampling, and the need for frequent blood sampling for laboratory analysis in the critically ill patient. Cycled oscillometric blood pressure measurement (i.e., an external blood pressure cuff) may be insufficient to gauge rapid

hemodynamic changes in critically ill hypertensive or hypotensive patients. External blood pressure cuffs may be ineffective in patients with severe burns or trauma. Continuous blood pressure monitoring facilitates titration of rapid-acting vasodilators and vasopressors. The accuracy of auscultated or oscillometric blood pressure readings under conditions of severe malperfusion or shock is suspect.^{2,3} Centrally measured aortic pressure is the true gold standard.^{2,3} Peripheral arterial pressure measured with an intraarterial catheter connected to a pressure transducer is the next best gauge given the impracticality of measurement of aortic pressure.

CONTRAINDICATIONS

Contraindications to arterial puncture and catheter placement relate primarily to abnormalities at the insertion sites. There are no absolute contraindications to arterial puncture or catheterization. Avoid skin and arteries that are already compromised by burns, infection, previous surgery in the area, severe dermatitis, severe peripheral vascular disease, or trauma.^{2,14} Puncture or cannulation of synthetic vascular grafts is relatively contraindicated. **Do not puncture where the artery “should be” if the arterial pulsation cannot be palpated.** Attempts at cannulation of nonpalpable arteries are generally fruitless and sometimes hazardous. Arterial puncture or catheterization is relatively contraindicated in patients with bleeding diatheses. Consider whether arterial access is really needed in those who have received or may receive thrombolytic therapy.

EQUIPMENT

■ ARTERIAL PUNCTURE FOR SINGLE ABG SAMPLE

- Povidone iodine or chlorhexidine solution
- Dorsal wrist extensor splint or small rolled up towel (**Figures 72-5, 72-6, and 72-7**)
- 1% lidocaine, 1 mL in a tuberculin syringe
- 5 mL syringe for blood collection with cap retained
- Prepackaged blood gas syringe with lyophilized heparin pellet
- 20 to 22 gauge needle for arterial puncture
- 1 to 2 mL of heparin (1000 U/mL)
- Gauze pads
- Adhesive tape
- Specimen collection bag or cup with 2 to 3 inches of ice

■ ARTERIAL (BRACHIAL, RADIAL, OR DORSALIS PEDIS) CANNULATION

- Povidone iodine or chlorhexidine solution
- Dorsal wrist extensor splint or small rolled up towel (**Figures 72-5, 72-6, and 72-7**)
- 1% lidocaine, 1 mL in a tuberculin syringe
- 4 × 4 gauze squares
- Adhesive tape
- Nylon suture, 3-0 or 4-0
- Needle drivers
- 20 or 22 gauge, 1¼ inch polyurethane angiocatheter or catheter-over-the-needle
- 0.45 mm diameter, 5¼ inch spring wire guide compatible with above catheter
- Sterile dressing to cover cannula

FIGURE 72-6. Correct positioning for radial artery puncture and cannulation. Dorsiflexing the wrist and supporting it with a small towel facilitate palpation of the artery and provide maximum working space. The needle or catheter-over-the-needle is aimed toward the oncoming blood flow at a 30° to 45° angle to the skin.

FIGURE 72-7. Radial artery puncture for an ABG sample. **A.** The pulse is palpated with the non-dominant hand. The heparinized syringe is inserted at a 30° to 45° angle to the skin surface. **B.** Arterial blood fills the syringe.

■ FEMORAL ARTERY CANNULATION

- Povidone iodine or chlorhexidine solution
- 1% lidocaine, 3 mL in a syringe armed with a 25 gauge needle
- 4 × 4 gauze squares
- #11 scalpel blade
- Nylon suture, 3-0 or 4-0 and needle drivers
- Femoral artery needle, approximately 18 gauge and 3 inches long
- 4 French single lumen catheter, at least 15 cm in length
- 30 cm guidewire compatible with above needle and catheter
- Sterile dressing to cover cannula

■ ULTRASOUND GUIDANCE

- US machine
- 5 to 10 MHz linear array US transducer
- Sterile US gel
- Sterile US transducer cover

It is necessary to prepare the syringe using heparin solution if a syringe that has not been designed specifically for ABG sampling is used, it has not been pretreated with heparin, or it does not contain a lyophilized heparin pellet. Draw up 1 to 2 mL of heparin solution into the syringe and then expel the heparin, leaving only the heparin remaining in the dead space of the syringe and the needle. This amount of heparin is sufficient to prevent clotting of the sample.¹⁴ It is important to remove all but the necessary amount of heparin as excess heparin has been found to falsely lower the PCO₂ measurement and may elevate the PO₂ measurement.²¹

Commercially produced, prepackaged kits are available for arterial puncture and arterial cannulation (**Figure 72-8**). These kits are complete and contain all the required equipment. Also available are

A

B

FIGURE 72-8. A commercially available arterial line kit. **A.** The kit. **B.** The catheter-needle-guidewire unit.

individually packaged heparinized ABG syringes and arterial line catheters in various sizes.

The catheter size used for the procedure will vary by patient age and the artery chosen to cannulate. Use a 22 or 24 gauge catheter for the radial or dorsalis pedis arteries and an 18 or 20 gauge for the femoral artery in neonates and infants. Use a 22 gauge catheter for the radial or dorsalis pedis arteries and a 16 to 20 gauge for the femoral artery in children up to 8 to 10 years of age. Use a 20 or 22 gauge catheter for the radial or dorsalis pedis arteries and a 14 to 20 gauge for the femoral artery in a larger child, adolescent, or adult.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain an informed consent unless the procedure is being performed emergently or the patient is unable to give consent. Document the informed consent or the reason why informed consent was not obtained in the medical record. Palpate the arterial pulse at the intended skin puncture site. Clean the skin of any dirt and debris. Cleanse the skin with chlorhexidine or povidone iodine solution and allow it to dry. There is some evidence that chlorhexidine is better than povidone iodine to prevent postprocedure infection.^{22,23}

Studies that examined the use of a topical anesthetic agents have not shown a benefit that outweighs the delay required to perform the procedure in emergent situations.²⁴ The use of an injectable local anesthetic agent may greatly aid arterial puncture, aid in arterial cannulation, and significantly reduce patient discomfort.²⁵ Infiltrate 1 mL of local anesthetic solution subcutaneously over the brachial, dorsalis pedis, or radial arteries. Infiltrate 2 to 5 mL of local anesthetic solution subcutaneously and into the subcutaneous tissues over the femoral artery. **Aspirate before infiltrating the local anesthetic solution to prevent inadvertent intravascular injection.**

Descriptions of the anatomy for arterial puncture or cannulation sites have been described in detail earlier in this chapter. The preferred site for the initial attempt at arterial puncture or cannulation is the radial artery.² Begin distally where the pulse is most palpable near the proximal wrist flexor crease. Reattempt the procedure more proximally along this same artery if the first attempt is unsuccessful and the pulse is still palpable. The radial artery on the contralateral wrist is a satisfactory second site for attempted access. Other acceptable second-attempt sites of access include the brachial, dorsalis pedis, and femoral arteries. **An attempt at ipsilateral ulnar artery catheterization is not advisable as both limbs of the hand's circulation may be compromised.** The discussion below focuses on puncture or cannulation of the radial and femoral arteries as over 90% of arterial punctures or cannulations occur at these sites.² The use of other sites generally follows the techniques described for the radial artery except the regional anatomic differences. Other rarely used sites include the posterior tibial and superficial temporal arteries.

TECHNIQUES

ARTERIAL PUNCTURE FOR A SINGLE SAMPLE

Position the patient to maximize exposure of the skin surface overlying the chosen artery. Dorsiflex the wrist and support this position with a small towel rolled up under the dorsal wrist surface or a commercial device (**Figures 72-5, 72-6, and 72-7**).²⁶ The patient's hand may be secured to an arm board or other rigid object with tape to facilitate a secure puncture site that will remain in the most advantageous position. Ensure that the elbow or hip is extended fully for brachial and femoral artery puncture. These positions provide maximum exposure and working area for the procedure. Locate the

chosen artery, prep the overlying skin, and infiltrate local anesthetic solution subcutaneously.

Reidentify the pulse by palpation with the nondominant hand using sterile technique (**Figure 72-7A**). Grasp the heparinized syringe with the dominant hand. Withdraw the plunger of the syringe so that 1 to 3 mL of air space is available in the syringe. This will allow for easier assessment of arterial blood return. Insert the needle at a 30° to 45° angle to the skin and just above the arterial pulse (**Figure 72-6**). Advance the needle through the skin until blood enters the syringe (**Figure 72-7B**). The blood flow will generally fill the syringe without necessitating the withdrawal of the plunger in a patient with a brisk pulse. Slowly withdraw the needle if no blood return occurs and watch for blood flow into the syringe.

If it is necessary to redirect the needle, it is imperative to first withdraw the needle until the tip is just below the skin surface before changing the angle to avoid lacerating the artery or adjacent structures. Collect at least 1 mL of blood in a prepackaged syringe or 3 mL of blood if preparing your own syringe with heparin to minimize the possibility of error due to the presence of heparin.¹⁴

Withdraw the needle after the arterial sample has been collected. Apply pressure to the puncture site for 3 to 5 minutes followed by a bandage or gauze dressing. Carefully remove the needle from the syringe if not using a safety needle. Evacuate any air from the syringe and apply a cap on the syringe. Place the syringe on ice for immediate transportation to the laboratory. Recheck the skin puncture site in 5 to 10 minutes to assess for the formation of a hematoma and/or vascular compromise to the distal extremity.

RADIAL ARTERY CANNULATION: CATHETER-OVER-THE-NEEDLE TECHNIQUE

The most basic method is direct introduction of the catheter-over-the-needle (i.e., angiocatheter) like inserting an intravenous catheter (**Figures 72-6 and 72-9**). This method is as effective as the more specialized wire-guided catheter technique, except in situations where the pulse is weak, the pulse is absent, or in the hands of more experienced operators.^{26,27}

Clean, prep, and identify the radial artery. Insert the catheter-over-the-needle at a 30° to 45° angle to the skin and directly over the arterial pulse (**Figures 72-6 and 72-9A**). Advance the catheter-over-the-needle into the artery (**Figure 72-9A**). Bright red blood in the hub of the needle indicates that the tip of the needle is within the artery. Advance the catheter-over-the-needle another 1 to 2 mm to ensure that the catheter tip is completely within the arterial lumen. Securely hold the hub of the needle. Advance the catheter over the needle until its hub is against the skin (**Figure 72-9B**). Remove the needle and confirm pulsatile arterial flow from the hub of the catheter. **Free-flowing pulsatile blood confirms proper catheter placement within the artery.** Apply a stopcock or intravenous extension tubing to the hub of the catheter. Secure the catheter by suturing it to the skin or by using commercially available devices that do not require suturing. Apply a dressing to the skin puncture site. Using a self-adherent dressing that contain a chlorhexidine-impregnated patch may reduce catheter-related bloodstream infection.^{28,29}

RADIAL ARTERY CANNULATION: SELDINGER-TYPE, SINGLE ARTERIAL WALL PUNCTURE

The second technique for arterial cannulation is a Seldinger-type technique (i.e., catheter-over-the-wire) using prepackaged commercially available kits. A commercially available one-piece catheter-over-the-needle kit is very popular (**Figures 72-8 and 72-10**). These wire-guided catheters have not been shown to increase successful cannulation or reduce the number of attempts except in situations

FIGURE 72-9. The catheter-over-the-needle technique for arterial cannulation. **A.** The unit is held at a 30° to 45° angle to the skin and advanced into the artery. **B.** The catheter is advanced over the needle and into the artery.

where a weak or absent pulse is present or with more experienced Physicians.^{26,27} **The guidewire can be useful in salvaging an arterial line when a catheter-over-the-needle cannot be effectively advanced.**

Open the package, remove the unit, and remove the protective cover over the needle. Advance and retract the guidewire to confirm it moves smoothly and does not get caught on the needle (**Figure 61-15**). Retract the guidewire as far back as possible. Identify the arterial pulse with the nondominant hand. Insert the catheter-over-the-needle through the skin and into the artery using a slow and continuous forward motion (**Figure 72-10A**). A flash of blood in the hub of the needle confirms successful entry through the arterial wall and into the vessel lumen. Stabilize the catheter-over-the-needle.

Advance the guidewire through the needle by pushing the actuating lever as far as possible toward the needle (**Figure 72-10B**). **Immediately stop if resistance is encountered while advancing the guidewire. The guidewire may be within the artery wall or through the artery wall and into the perivascular tissue. Do not try to force the guidewire into the vessel. Do not retract the guidewire. Withdraw the entire unit and apply pressure to the puncture site to prevent a hematoma. Obtain a new kit and repeat the procedure.**

The guidewire is successfully within the arterial lumen once advanced. Firmly grasp the clear hub of the needle and advance the catheter over the guidewire and into the artery (**Figure 72-10C**). **A rotating motion of the catheter is often helpful to advance it if difficulty is encountered. Securely hold the catheter at the level**

FIGURE 72-10. Catheter-over-the-needle technique using a commercially available one-piece unit. **A.** The catheter-over-the-needle is inserted into the artery. **B.** The guidewire is advanced through the needle and into the artery. **C.** The catheter is advanced over the guidewire into the artery with a twisting motion.

of the skin. Firmly hold the catheter hub and remove the guidewire, needle, and feed tube assembly as a unit. Free-flowing pulsatile blood confirms proper catheter placement within the artery. Apply a stopcock or intravenous extension tubing to the hub of the catheter. Secure the catheter by suturing it to the skin or by using commercially available devices that do not require suturing. Apply a dressing to the skin puncture site.

A commercially available Seldinger-type catheter-over-the-needle kit is an alternative to the one-piece unit.³⁰ This is similar to the familiar central venous access kit (**Figure 63-9**). Open the package and review the equipment it contains. Place the finder needle on the syringe. Withdraw the plunger 1 cm to break the bead of the syringe. Identify the arterial pulse by palpation with the nondominant hand. Insert the needle through the skin and into the artery using a slow and continuous forward motion (**Figure 72-11A**). A flash of blood in the syringe confirms the successful entry through the arterial wall and into the vessel lumen. Firmly hold and stabilize the needle. Remove the syringe. Advance the guidewire through the needle (**Figure 72-11B**). **The guidewire should advance without resistance. Immediately stop if resistance is encountered while advancing the guidewire. The guidewire may be within the artery wall or through the artery wall and into the perivascular tissue. Do not try to force the guidewire into the vessel. Do not retract the guidewire to prevent shearing off a piece of the guidewire.**

FIGURE 72-11. The Seldinger technique for arterial catheterization. **A.** The needle is inserted into the artery. **B.** The syringe has been removed from the needle. The guidewire is advanced through the needle and into the artery. **C.** The needle is removed while leaving the guidewire in place. **D.** The skin is punctured with a #11 scalpel blade to allow easy insertion of the catheter. **E.** The catheter is advanced over the guidewire and into the artery. **F.** The guidewire is removed.

Withdraw the entire unit and apply pressure to the puncture site to prevent a hematoma. Obtain a new kit and repeat the procedure. Withdraw the needle while leaving the guidewire in place (**Figure 72-11C**). **Do not readvance the needle as it can shear off a**

piece of the guidewire. Make a 3 mm puncture wound next to the skin puncture site of the guidewire using a #11 scalpel blade to facilitate inserting the catheter (**Figure 72-11D**). Thread the catheter over the guidewire. Advance the catheter over the guidewire until

the hub of the catheter is against the skin (**Figure 72-11E**). A **rotating motion of the catheter is often helpful to advance it if difficulty is encountered**. Securely hold the catheter at the level of the skin. Remove the guidewire while firmly holding the catheter hub against the skin (**Figure 72-11F**). Free-flowing pulsatile blood confirms proper catheter placement within the artery. Apply a stopcock or intravenous extension tubing to the hub of the catheter. Secure the catheter by suturing it to the skin. Apply a dressing to the site.

RADIAL ARTERY CANNULATION: SELDINGER-TYPE, DOUBLE ARTERIAL WALL PUNCTURE

While localization and needle puncture of the artery are identical in all three techniques, commonly encountered difficulties include threading of the catheter with the first technique and threading of the guidewire into the vessel lumen with the second technique. Blood may enter and rise through the needle if the needle orifice is merely at the vessel edge. The catheter may get hung up outside the lumen with the catheter-over-the-needle technique when trying to advance it.³¹ The guidewire may not easily pass or may dissect into the vessel wall creating a false lumen when using the Seldinger-type single arterial wall puncture technique. Pulsatile flow is more easily confirmed prior to the passage of the guidewire. This third technique in which both walls of the radial artery are punctured may offer an advantage in passing the guidewire and catheter into the arterial lumen.

Assume a position out of the trajectory line of the catheter to avoid being sprayed with blood when using this technique. This method is a Seldinger-type technique that uses a guidewire separate from the catheter-over-the-needle. Locate the arterial pulse and insert the catheter-over-the-needle into the artery. Immediately and continuously advance the catheter-over-the-needle through the posterior wall as confirmed by no blood exiting the needle hub. Withdraw the needle while leaving the catheter in place through the artery. Flatten the angle of the catheter to the skin to less than 30°. Hold the tip of the guidewire poised at the hub of the catheter. Slowly withdraw the catheter with the nondominant hand. Promptly insert the guidewire through the catheter and into the artery when pulsatile blood flow is noted from the hub of the catheter. Advance the catheter over the guidewire and into the lumen of

the artery. Withdraw the guidewire and apply a stopcock or intravenous extension tubing. Secure the catheter and apply a bandage or dressing.

This double-puncture technique for cannulation theoretically may be associated with greater vascular damage. Reserve this technique for instances in which the prior two arterial cannulation techniques have been unsuccessful. Investigators found no difference in complications when using this technique compared to other techniques.³²

FEMORAL ARTERY CANNULATION

The femoral artery may be cannulated if the radial artery is inaccessible or attempts at cannulation are unsuccessful. A longer catheter, catheter-over-the-needle, and needle are required as the femoral artery is not superficial. Slightly abduct the patient's leg and identify the femoral artery pulse. Prep, drape, and anesthetize the skin and subcutaneous tissues. Maintain the fingers of the nondominant hand on the arterial pulse. Insert the needle or the catheter-over-the-needle at a 45° angle to the skin with the needle bevel pointing superiorly and into the femoral artery. The remainder of the technique is as described previously.

DORSALIS PEDIS ARTERY CANNULATION

The procedure for cannulation of the dorsalis pedis artery is the same as that described for the radial artery. Clean, prep, and plantar flex the foot. Do not plantar flex the foot more than 45° as this can stretch and occlude the artery. The needle angle of entry should be less than that used for the radial artery due to the superficial location of the artery. Insert it at 20° to 30° to the skin rather than 30° to 45°.

ULTRASOUND-GUIDED ARTERIAL CANNULATION

US can be used to guide arterial puncture or cannulation (**Figures 72-12 through 72-15**). It can be a rescue method if the palpation technique fails. It can be used initially to decrease the number of puncture attempts, to decrease the amount of time spent gaining access, and to decrease complications (e.g., arterial laceration and

A

B

FIGURE 72-12. Ultrasound-guided radial arterial puncture. **A.** Short axis image of the radial artery (yellow circle). **B.** Short axis image of the radial artery under compression. Note that it hardly compresses (yellow circle).

FIGURE 72-13. Ultrasound-guided radial arterial puncture. Short axis image of the radial artery with the needle approaching (yellow arrow).

FIGURE 72-15. Ultrasound-guided radial arterial puncture. Short axis image of the radial artery with a needle inside (yellow circle). Note the artifact from the needle.

hematomas).^{11,12,33-41} There is some conflicting evidence that the use of US does not decrease the number of puncture attempts.^{42,43} Most studies have focused on radial artery cannulation, but the technique for alternative sites is the same.⁴⁴ US as an adjunct to radial artery cannulation is considered best practice by some experts.³⁵

Clean and prep the skin over the artery. Prepare the US transducer. Have an assistant apply US gel over the footprint of the transducer. Instruct the assistant to place the gel-coated US transducer in the sterile cover while you hold it. Have the assistant place sterile ultrasound gel over the target artery. Orient the transducer marker on the side of the transducer so it matches that on the screen. Identify the artery. It will appear as a round, thick-walled vessel that is not easily compressible and exhibits a pulsatile nature when compressed (**Figure 72-12A**). Move the transducer proximally and distally over the artery to approximate its course, which is sometimes not perfectly parallel to the long axis of the extremity. Use Doppler flow to assist identifying arterial structures in low-flow or hypovolemic patients. Center the target artery on the screen. The center of the transducer is now directly over the vessel and can act as a guide

to skin puncture. Hold the transducer with the nondominant hand or have an assistant hold the transducer.

Insert the catheter 1 to 2 cm distal to the transducer. Rock the needle in the subcutaneous tissue very slightly to create movement that is apparent on the screen. This will help to identify the location of the needle in relation to the artery. Slowly advance the needle once the tip of the needle has been identified (**Figure 72-13**). Move the transducer proximally and advance it until the needle tip is visible. This technique will help prevent advancing the needle beyond the view of the US and misidentifying the shaft of the needle as the tip. **The needle may not be apparent, but motion through the tissue can be used to infer the site of the needle tip.**

The needle will dimple the wall of the artery when it reaches the arterial wall. Advance the needle slowly while watching for the flash of blood in the needle hub. Continue to advance the needle into the artery (**Figure 72-14**). Use US to confirm placement of the needle and/or catheter within the artery (**Figure 72-15**). Proceed from this point with either the catheter-over-the-needle or the Seldinger-type technique to complete the procedure.

A

B

FIGURE 72-14. Ultrasound-guided radial arterial puncture. **A.** Long axis image of the radial artery between the yellow lines. **B.** Long axis image of the radial artery with the needle inserted (yellow arrow).

ALTERNATIVE TECHNIQUE

A cutdown technique may be performed to cannulate an artery. It is primarily used for the brachial, femoral, or radial arteries but may be used to access other peripheral arteries. This technique is rarely required with the availability of US to locate an artery. The technique is briefly described. Please refer to Chapter 69 for the complete details.

Clean, prep, anesthetize, and drape the skin overlying the chosen artery. Make a 1.5 to 2.0 cm transverse skin incision centered over the artery. **Do not cut into the subcutaneous tissue so that blood vessels, nerves, and tendons are not transected.** Spread the subcutaneous tissues parallel to the artery with a mosquito hemostat. Expose 1.0 cm of the length of the artery. Pass a silk suture under the proximal end of the exposed artery. Insert a catheter-over-the-needle through the skin just distal to the incision and advance it into the incision. Elevate the suture to control the artery and occlude distal blood flow. Advance the catheter-over-the-needle into the artery. Release the suture and advance the catheter into the artery. The remainder of the procedure is as described previously. Apply pressure over the incision site for 5 to 10 minutes to prevent the formation of a hematoma or seroma.

AFTERCARE

Apply direct pressure for 3 to 5 minutes to the skin puncture site after an arterial puncture or removal of an arterial catheter. Apply direct pressure for 10 minutes or more if the patient has a bleeding diathesis or has received thrombolytic therapy. Apply a bandage or gauze dressing to the skin puncture site. Reassess the skin puncture site in 15 minutes for continued bleeding or hematoma formation.

An arterial catheter must be secured to the skin to prevent inadvertent dislodgement, hematoma formation, and exsanguination. Sew the hub of the catheter to the skin using 3-0 or 4-0 nylon sutures. Apply a clear protective dressing (e.g., Tegaderm) over the site that will allow for monitoring of the cannulation site. Use a splinting device to secure the limb in the desired position for optimal monitoring if the catheter is in the wrist, arm, or foot (**Figure 72-5**).

Monitor the site regularly to assess for signs of arterial thrombosis, bleeding, catheter dislodgement, hematoma formation, or infection. Assess the extremity distal to the catheter for evidence of ischemia. Replace the dressing regularly in accordance with institutional guidelines.

Flush the arterial catheter with sterile saline solution. Heparinized saline was the standard arterial line flush solution in the past.⁴⁵ The use of heparinized saline has not been shown to improve functionality, prevent thrombotic complications, or increase the duration of catheter patency when compared to saline.⁴⁵ The use of heparin risks an adverse reaction or heparin-induced thrombocytopenia.

COMPLICATIONS

Arterial puncture and catheterization are generally safe procedures with an incidence of clinically significant complications of less than 5%.² The primary complications of arterial catheterization are arterial injury, arterial thrombosis, bleeding, and infection.^{3,4,46-54} Secondary bacteremia and septic emboli may occur, but infection is usually limited to the site of catheterization. The risk of catheter site infection is linearly related to the length of time the catheter is in place.³ The infection rate is similar for femoral and radial artery sites.^{3,8,9,48,55} Nerve injury from direct puncture of the nerve

has been reported.⁵⁶ Multiple cases of neuropathy have occurred from a hematoma formation and subsequent nerve compression.²¹ Apply at least 3 minutes of direct pressure to radial, brachial, and dorsalis pedis puncture sites and 5 to 10 minutes of pressure to the femoral site to minimize hematoma formation after arterial puncture or arterial catheter removal.^{56,57} Small hematomas are common after arterial puncture. Major bleeding is unusual and generally occurs only in the concealed retroperitoneum after femoral artery puncture or cannulation.⁵⁸ Angiographically demonstrable thrombosis is common in 25% to 40% of patients after prolonged arterial catheterization.³ This rarely results in clinically significant morbidity. Secondary limb ischemia and necrosis requiring amputation occur in less than 1 in 2000 arterial catheterizations.^{3,4,13,59} Other rare complications include the formation of an arteriovenous fistula or pseudoaneurysm.^{38,39,60}

The complications associated with an arterial catheter can be limited.^{13,61} Only insert an arterial catheter if it is truly needed. Always insert it using strict aseptic technique. Remove the catheter as soon as it is determined that it is no longer required to assist in the management of the patient. Frequently check the skin puncture site for signs of bleeding, a hematoma, and an infection. Frequently assess the distal extremity for signs of perfusion. Remove the catheter at the first sign of a complication. Place the catheter in the patient's nondominant hand, if known, to limit the impact of any complications.

SUMMARY

Arterial puncture and cannulation are quick, safe, and simple to perform. Arterial blood sampling may aid in determining the acid-base status and ventilator management of critically ill patients. An arterial catheter is appropriate in patients who need continuous monitoring of arterial blood pressure or frequent ABGs or in patients in whom indirect blood pressure monitoring is not possible. Avoid arterial puncture and cannulation in skin areas with evidence of burn, infection, severe dermatitis, severe peripheral vascular disease, or trauma. Palpation of the arterial pulse and correct anatomic positioning are necessary before these procedures are attempted. It is necessary to monitor the cannulated site for signs of bleeding, hematoma, infection, or thrombosis. Always apply direct pressure to the skin puncture site after an arterial puncture or removal of an arterial catheter.

Extracorporeal Membrane Oxygenation

Jean W. Hoffman and Jordan R. H. Hoffman

INTRODUCTION

Extracorporeal life support (ECLS) has been used as a rescue therapy for patients presenting with acute cardiopulmonary failure. The use of ambulatory extracorporeal support parallels the growth and development of cardiopulmonary bypass during open heart surgery over the past 40 years. The first successful use of a cardiopulmonary bypass circuit occurred in the early 1950s.¹ It was not until 1971 that an extracorporeal membrane oxygenator was used for an extended period to support a patient with “shock-lung syndrome.”² Portable extracorporeal membrane oxygenation (ECMO) was used in the late 1970s to rescue 39 patients with a variety of conditions (e.g., cardiac trauma, cardiogenic shock after myocardial infarction, drug overdose, and massive pulmonary embolus).³ Portable cardiopulmonary support was largely abandoned due to poor outcomes after early reports.

Literature supporting the initiation of ECMO in adult medical patients comes from two modern trials examining outcomes in patients with acute respiratory distress syndrome (ARDS) and refractory cardiac arrest.^{4,5} The literature supporting the use of ECMO remains sparse with only scattered case reports published over the past 10 years. Hesitancy to embrace ECMO as a rescue therapy in the adult surgical patient has been partially due to the need for therapeutic anticoagulation to maintain the bypass circuit. There are an increasing number of surgical patients being treated with “high-flow, no-heparin” ECLS to improve survival.⁶

Survival after initiation of ECMO is closely correlated with the indication for which ECLS was initiated.⁷ The prognosis is related to baseline functional status, medical comorbidities, operative history, and the duration of ECLS.^{8,9} These and other factors (e.g., body habitus, multiorgan failure, neurologic status, or terminal conditions) may influence outcomes prior to cannulation. **The Emergency Physician should anticipate the goals of therapy.** Will ECLS be used as a bridge to treatment (e.g., percutaneous intervention for coronary disease), as a bridge to recovery (e.g., severe ARDS), or as a bridge to transplant? These concepts are occasionally not mutually exclusive and are accomplished jointly. ECLS may be contraindicated if the underlying problem is not reversible with the help of ECMO.

Approach cannulation for ECLS in the Emergency Department cautiously. ECLS should only be performed by Emergency Physicians with experience in its initiation, maintenance, and discontinuation.⁷ Multiple organizations offer training courses in ECMO cannulation and management. The Emergency Physician can sterilely place central venous and arterial lines while waiting for the Cardiothoracic Surgeon to arrive for cannulation (Chapters 63 and 72).^{10,11} The Emergency Physician can initiate and perform ECMO for the patient in cardiac arrest.¹⁰⁻¹³ It is up to individual hospitals to maintain up-to-date records for purposes of tracking outcomes and Emergency Physician credentialing.

Guidelines for the development of an ECMO program are beyond on the scope of this chapter but can be found through the Extracorporeal Life Support Organization (ELSO) website.¹⁴ An ECMO program requires coordination between multiple departments and specialists so resource allocation occurs efficiently and justly. Successful ECMO programs can balance optimal care with the ability to provide advanced therapies to patients in need.

ANATOMY AND PATHOPHYSIOLOGY

CARDIAC FAILURE

Heart failure is the inability of the heart to propel blood at a rate equal to the metabolic needs generated by peripheral tissues. It can be classified by the presence or absence of a reduced ejection fraction, the ventricle affected (i.e., right heart failure, left heart failure, or biventricular failure), and the chronicity (i.e., acute, chronic, or acute-on-chronic).

The normal heart maintains several adaptive mechanisms to compensate for chronic decompensation. These mechanisms include enhanced contractility with activation of neurohumoral responses (e.g., the release of epinephrine and norepinephrine, activation of the renin-angiotensin-aldosterone system, or release of natriuretic peptides), compensatory structural changes (e.g., muscular hypertrophy), and rising preload (i.e., Frank-Starling mechanism).¹⁵

Acute heart failure is caused by conditions in which the heart is abruptly presented with a load that exceeds its capacity to function or filling is impaired. Chronic heart failure occurs because of a slowly developing intrinsic defect in myocardial contraction.¹⁵ The indications for veno-arterial (V-A) ECMO cannulation in the Emergency Department are limited to acute or acute-on-chronic heart failure.

RESPIRATORY FAILURE

Respiratory failure is defined as an inability to exchange oxygen across the capillary and alveolar membranes, leading to hypoxemia. Respiratory failure can be classified by its chronicity (i.e., acute, chronic, or acute-on-chronic). It is broadly attributed to extrinsic compression, lower airway disease, neuromuscular disease, upper airway disease, or vascular occlusion. Indications for veno-venous (V-V) ECMO cannulation in the Emergency Department are limited to acute or acute-on-chronic respiratory failure.

ARDS remains the most well-studied indication for V-V ECMO. The conditions leading to the development of ARDS are numerous (**Table 73-1**).¹⁵⁻³⁷ The causes of ARDS share a similar final pathophysiologic pathway that culminates in activation of proinflammatory mediators, formation of a hyaline membrane impairing oxygen diffusion across the capillary-alveolar interface, pneumocyte destruction, and sloughed bronchoalveolar epithelium (**Figure 73-1**).²⁸

TABLE 73-1 Conditions Leading to ARDS*

Acetylsalicylic acid	Lung irritant chemicals
Barbiturates	Lung irritant gasses
Burns	Lung irritants inhaled
Cardiopulmonary bypass	Methadone
Diffuse lung infections	Near-drowning
Miliary tuberculosis	Organic solvents
<i>Mycoplasma</i>	Oxygen toxicity
Pneumocystis	Pancreatitis
Viral	Paraquat
Disseminated intravascular coagulation	Poisoning
Drugs	Pulmonary contusion
Fat embolism associated with fractures	Sepsis
Gastric aspiration	Smoke
Heroin	Transfusion-associated lung injury
Hypothermia	Trauma
Hypothermia rewarming	Uremia
Ionizing radiation	

*Many of these are associated with the development of ARDS.

ECMO

ECMO circuits are composed of an oxygenator or artificial lung, a gas blender, a heat exchanger, cannula and tubing, monitoring equipment, and a blood pump (**Figure 73-2**). The gas blender mixes different concentrations of air, carbon dioxide, and oxygen and forces the mixture to the oxygenator. The oxygenator mixes the patient's blood in the ECMO circuit with the gas from the blender and oxygenates the blood.

Cannulation strategies can be peripheral or central. Peripheral cannulation requires placement of a drainage cannula in the femoral or jugular vein to remove blood from the body. Oxygenated blood can be returned via a return cannula to either an artery (e.g., V-A ECMO) or a vein (e.g., V-V ECMO). V-V ECMO relies on a working heart to deliver oxygenated blood to the patient's circulatory system. V-A ECMO bypasses the heart, and the ECMO circuit provides delivery of oxygenated blood to the patient's circulatory system. Central cannulation is the placement of drainage and return cannulas into a central artery or central vein. It requires the performance of a median sternotomy or thoracotomy. Additional cannulation strategies can include a combination of central and peripheral cannulation.

Blood flows of up to 8 L/min can be delivered under ideal circumstances using a centrifugal pump. Human physiology is described by Poiseuille's law. It dictates that flow within the ECMO circuit is a function of the radius of the cannulas chosen, length of the ECMO circuit tubing, viscosity of the blood, and pressure

gradient generated by the centrifugal pump. **Make every effort to choose cannulas that will maximize flow. The flow is commonly the limiting factor to delivery of oxygenated blood via the return cannula.** The operator typically sets a desired pump rotation per minute (RPM) or speed that determines the blood flow within the circuit and to the body. Flow can be measured directly off the tubing for confirmation.

ECMO is designed for a longer duration of use compared to cardiopulmonary bypass. There is no reservoir in ECMO. All products must be given as a transfusion through a separate line. The physiologic monitoring of the ECMO circuit is complex and will be discussed throughout this chapter.

VENO-VENOUS ECMO

INDICATIONS

V-V ECMO is indicated in adults, children, and pregnant patients for acute respiratory failure or acute-on-chronic respiratory failure causing high airway pressures, refractory hypoxemia, and refractory hypercarbia (**Table 73-1** and **Figure 73-2B**).¹⁵⁻³⁷ The most widely accepted indication for V-V ECMO is ARDS refractory to maximal medical therapy. Determining which patients with ARDS should receive ECMO can be difficult. Trials have incorporated the lung injury score (i.e., the Murray score) to attempt to provide a uniform indication for consideration of ECMO.³⁸

FIGURE 73-2. ECMO. **A.** An example of a circuit. (Used from Jurgen Schaub, <https://commons.wikimedia.org>.) **B.** Cannulation for V-V ECMO (left) and V-A ECMO (right). (Photo used with permission from reference 28.)

The lung injury score was designed to characterize the presence and extent of pulmonary damage in ARDS.³⁸ The score incorporates airway pressures, oxygenation, and radiographic findings (**Table 73-2**). Ventilation is not a component of this scoring system. Higher scores indicate higher ARDS-specific mortality. A lung injury score greater than 3 in the CESAR trial indicated a potential survival benefit with the addition of V-V ECMO compared to optimal medical management.⁴ V-V ECMO should be considered when the patient's lung injury score is 2 (i.e., a mortality of > 50%) and is indicated when the lung injury score is ≥ 3 (i.e., a mortality of > 80%).¹⁴

Virtually any condition leading to ARDS represents a potential indication for V-V ECMO (**Table 73-1**). Patients with chronic respiratory failure can be candidates for V-V ECMO as a bridge to transplantation. Initiation of V-V ECMO in this population is outside the scope of the Emergency Department. It should only be performed at institutions after consultation with the lung transplant team.

CONTRAINDICATIONS

An absolute contraindication to V-V ECMO initiation is an underlying disease process that is progressive and irreversible. Examples include chronic severe pulmonary arterial hypertension with evidence of right heart dysfunction, permanent neurologic damage, severely depressed functional status, and terminal malignancy.

Relative contraindications differ between institutions but typically include age greater than 75 years old, certain hemoglobinopathies, inability to be anticoagulated, an innate or pharmacologically induced immunocompromised state, multisystem organ failure, and recoverable central nervous system (CNS) injury. ECMO can be safely managed without anticoagulation in the short term depending on institutional policy.²¹ Obesity can present a technical challenge to ECMO cannulation. The initiation and maintenance of ECMO in obese patients is feasible and safe.³⁹

TABLE 73-2 The Lung Injury Score (i.e., Murray Score)

Component	Characteristic	Lung injury value
Chest Radiography	No consolidation	0
	Alveolar consolidation in 1 quadrant	1
	Alveolar consolidation in 2 quadrants	2
	Alveolar consolidation in 3 quadrants	3
	Alveolar consolidation in 4 quadrants	4
Hypoxemia	$\text{PaO}_2/\text{FIO}_2 \geq 300$	0
	$\text{PaO}_2/\text{FIO}_2$ 225–299	1
	$\text{PaO}_2/\text{FIO}_2$ 175–224	2
	$\text{PaO}_2/\text{FIO}_2$ 100–174	3
	$\text{PaO}_2/\text{FIO}_2 < 100$	4
Positive end-expiratory pressure (when ventilated)	$\geq 5 \text{ cmH}_2\text{O}$	0
	6–8 cmH_2O	1
	9–11 cmH_2O	2
	12–14 cmH_2O	3
	$\geq 15 \text{ cmH}_2\text{O}$	4
Respiratory system compliance score (when available)	$\geq 80 \text{ mL/cmH}_2\text{O}$	0
	60–79 $\text{mL/cmH}_2\text{O}$	1
	40–59 $\text{mL/cmH}_2\text{O}$	2
	20–39 $\text{mL/cmH}_2\text{O}$	3
	$\leq 19 \text{ mL/cmH}_2\text{O}$	4

The final value is obtained by adding the values and dividing by the number of components used.
No lung injury, score = 0.
Mild-to-moderate lung injury, score = 0.1–2.5.
Severe lung injury (ARDS), score > 2.5.
Source: Modified from reference 38.

EQUIPMENT

Keep the required ECMO equipment in one area. It is beneficial to have multiple portable ECMO carts fully stocked and always available. Have the primed portable ECMO system with crystalloid solution ready prior to cannulation. The contents of a comprehensive and fully stocked ECMO cart can be found in **Table 73-3**.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Discuss the goals of the ECMO procedure and outcomes. Immediate complications include cardiac perforation, damage to vessels or nerves, ECMO discontinuation or termination, embolic events, failure to wean from ECMO, life-threatening hemorrhage (e.g., cannula site bleeding, gastrointestinal bleeding, or intracranial hemorrhage), limb ischemia, local or systemic infection, need for further cannulation procedures, and death. Discuss the need for tracheostomy placement as an anticipated outcome. Obtain an informed consent for the procedure, and place this in the medical record.

Prepare for the procedure. Evaluate the echocardiogram data, radiology imaging, and laboratory values prior to cannulation. These results may alter the proposed plan. Position the patient to maximize the exposure of the vessels to be cannulated. Perform a “time out” to confirm the patient and the proposed procedure. Tuck the patient’s arms at their side unless additional arterial monitoring via the arm has not yet been established. Clean the skin at the site of cannulation of any dirt and debris. Apply chlorhexidine or povidone iodine solution and allow it to dry.

This procedure must be performed using strict sterile technique. Don full personal protective equipment (i.e., a hat, mask, eye protection, sterile gown, and sterile gloves) to protect from exposure to the patient’s blood and to protect the patient from an iatrogenic infection. Apply sterile drapes to delineate a sterile field. Administer a heparin bolus before or after cannulation followed by a continuous

TABLE 73-3 ECMO Supplies

General Supplies	Access Supplies and Dilators
Bedside sterile trash bag	Ultrasound machine
Half drapes (2)	Linear transducer
Sterile bowels (2)	Radiology C-arm
Laparotomy sponges	Sterile C-arm drape
Bandaging tape (1 roll)	Micropuncture kit
Sterile gowns	Dilators
Sterile gloves	Wires and Sheaths
Needle counter	Cope Mandril starter wire, 60 cm (2)
Ring basin	Guidewire, 180 cm (2)
Side drapes, two	Amplatz super stiff guidewire, 10 cm (2)
Scalpel with handles (#10, #11, and #15)	Hi-torque steelcore guidewire, 300 cm (2)
Syringes (10, 20, and 30 mL)	Access sheaths: 5, 6, and 7 French (2 each)
Bulb syringe	Flexor Check-Flo 10 French introducer sheath (2)
Table cover	Super Sheath XL 14 French introducer catheter (2)
Top drape	Percutaneous insertion kit with dilators (2)
Sterile towels (10)	Avalon insertion kit, 100 and 210 cm (2 each)
Suction tubing (2)	Cannulas
Double spike line	Avalon cannula, 23, 27, and 31 mm (2 each)
Tubing (1/4 and 1/8 inch)	Femoral arterial cannula, 19–25 French (2 each)
Monitor extension tubing (6 inch)	Femoral venous cannula, 19–25 French (2 each)
4-way stopcock (2)	Quickdraw venous cannula, 22 and 25 French (2 each)
Double male Luer lock (2)	Opsite arterial cannula, 16, 18, 20, and 22 French (2 each)
Umbilical tape, 30 inch (2)	Suture and Hemostatic Agents
Y connectors, 3/8 inch (2)	#1 Ethibond control release suture (8)
Straight connectors, 3/8 inch with Luer lock (2)	#0 silk ties, 30 inch (2 packs)
Straight connectors, 3/8 inch without Luer lock (2)	3–0 Prolene on RB-1 needle (6)
Zip ties (10)	4–0 Prolene on C-1 needle (6)
Kelly clamps (4)	5–0 Prolene on C-1 needle (6)
Hemostatic forceps (8)	Disposable clip applier, medium and large (2 each)
Towel clamps (8)	Surgicel or another topical hemostatic
Bag decanter	
Tegaderm, 4 × 4 inch (2)	
Gauze, 4 × 4 inch (10)	
Betadine	
Chloraprep stick, large (2)	
Saline bags, 1000 mL (2)	
Needles, 14 to 27 gauge	
Local anesthesia solution	
Heparinized saline, 1000 mL, 2 U/mL	

heparin infusion unless contraindicated. Monitoring and goal parameters differ between institutions and are discussed below.

Prepare the ultrasound transducer. Have an assistant apply ultrasound gel over the footprint of the transducer. Instruct the assistant to place the gel-coated transducer in the sterile cover while you hold it. Have the assistant place sterile ultrasound gel on the patient or transducer.

TECHNIQUE

ECMO initiation can be divided into several phases including patient preparation, access, dilation, cannulation and connection, initiation, and follow-up care. The use of the right internal jugular and right femoral veins are preferred for venous cannulation. These vessels tend to travel along a straighter course with the superior and inferior vena cava (Chapter 63 and **Figure 63-1**). Review any available imaging for variant anatomy or in situ venous thrombus, which may complicate catheter placement. The following technique can be generalized to all peripheral venous access sites. The technique describes one site, but two are required. The second site is cannulated like the first. The technique of obtaining

venous access is briefly described below. Refer to Chapter 63 for the complete details.

■ ACCESS

Begin by preparing the access site as described above. Infiltrate the dermal and subcutaneous tissues with local anesthetic solution in the areas of cannulation. Connect the micropuncture needle to a syringe. Penetrate the anterior wall of the vein at a 45° angle under ultrasound guidance (Chapter 64). **Enter the vein anteriorly.** Entrance to the vein from the side or a double wall stick can complicate passage of large dilators and cause hemorrhage once anticoagulation is initiated. Advance the needle into the vein (**Figure 63-10A**). The flow of blood indicates that the needle tip is within the vein. Hold and stabilize the needle. Carefully disconnect the syringe from the needle (**Figure 63-10B**). It is not uncommon to have no blood return once the negative pressure of the syringe is removed.

Pass the guidewire from the micropuncture set through the needle and into the lumen of the vein (**Figures 63-10B and 63-10C**). The guidewire should pass smoothly. Accurate placement can be confirmed with ultrasound or fluoroscopy. Remove the needle while securely holding the guidewire. Make a small skin incision with a #11 scalpel blade next to the guidewire (**Figure 63-10D**). Thread the dilator over the guidewire until its hub is against the skin (**Figure 63-10E**). A twisting motion of the sheath may be needed to insert the sheath. Hold the hub of the dilator against the patient's skin. Remove the guidewire. Insert the 60 cm wire through the dilator. Hold the wire securely and remove the dilator.

Make a skin incision with a #11 scalpel blade large enough to allow passage of cannulas of up to 28 French. Place a size 5, 6, or 7 French access sheath over the wire while maintaining a hold on the wire (**Figure 63-10F**). Insert the sheath until its hub is against the skin. A twisting motion of the sheath may be needed to insert the sheath. Remove the wire while securely holding the sheath (**Figure 63-10G**). Apply a syringe of saline to the Luer lock of the sheath. Aspirate the sheath and then flush it to free the sheath of air bubbles (**Figure 63-13**). Secure the sheath to the skin with suture. The access sheath can act as a central venous line for fluid and medication delivery until ready to proceed with dilation.

■ DILATION

Insert the 180 cm stiff wire through the back the access sheath. Excessive manipulation of this wire may cause a breakdown of the seal between the sheath and wire, leading to bleeding onto the surgical field. Securely hold the wire. Remove the access sheath. Hold pressure above and below the skin puncture site with the nondominant hand while stabilizing the wire and occluding the vessel. **It is essential to always remain in control of the wire.** Unintentional loss of the wire can lead to loss of access, accidental vessel or cardiac perforation, or malposition of the final cannula.

Dilate the tract and vessel serially using vascular dilators (**Figures 73-3 and 73-4A**) over the wire until a dilator 2 French sizes smaller than the chosen ECMO cannula size is used. For example, dilate to a 20 French transitional dilator if a 22 French cannula is planned. The wire should move freely through each dilator indicating no kinking of the wire or vessel wall injury. There should be only minimal resistance with passage of the dilators. **Never force the dilator into a vessel. Maintain firm pressure over the vessel between dilations to ensure no hemorrhage or hematoma formation.** Remove the dilator and repeat the dilation of the tract with a smaller dilator if resistance is met. Check the skin incision to ensure that there is no intervening skin bridge and that the incision is of adequate length to accommodate larger dilators.

FIGURE 73-3. Examples of vascular dilators.

■ CANNULATION AND CONNECTION

This is the next step once the tract and vessel are successfully dilated. Apply and hold pressure with the nondominant hand as the last dilator is removed. Insert the stiff support catheter supplied with the ECMO cannula into the back of the ECMO cannula. Flush the entire system with saline. Apply the venous ECMO cannula over the wire. Advance the ECMO cannula over the wire. Insert it into the patient with constant forward pressure. Blood will escape through the multiple ECMO cannula side holes as the cannula is inserted. The bleeding will stop once the cannula is fully inserted. Flush the cannula free of air. Check the final position of the cannula with bedside ultrasound, fluoroscopy, or transesophageal echocardiography. Secure the cannula into place in at least three different sites along the length of the ECMO catheter with figure-of-eight sutures.

Connect the ECMO cannula to the ECMO system tubing with either straight or “Y” connectors depending on the chosen cannula

A

B

FIGURE 73-5. Examples of a straight connector and a Y connector.

configuration (**Figure 73-5**). The use of tubing connectors with Luer lock adapters allows removal of fine air bubbles through a syringe once the system has been connected. Apply zip ties to secure the tubing to the ECMO catheters and tubing connectors.

■ INITIATION

The two venous access sites have been cannulated and connected to the ECMO circuit. Have a nurse prepare vasopressors prior to ECMO initiation to neutralize large hemodynamic swings. Have fluid and blood products available in case of excess blood loss prior to or during the cannulation. It is helpful to have additional large-bore peripheral intravenous or central venous access for medication and fluid administration. Place an arterial cannula in the right radial artery for blood pressure monitoring if not inserted prior to ECMO cannulation (Chapter 72). Provide sedation and pain control during and immediately after ECMO cannulation and initiation. Initiate ECLS. The operator can titrate the pump speed to a desired flow while monitoring the patient's hemodynamics. Place the patient on ventilator settings to reduce the risk of barotrauma once hemodynamic parameters and oxygenation are confirmed to be acceptable (Chapter 36).

■ SPECIAL CIRCUMSTANCES

A dual-lumen ECMO cannula can be placed (**Figure 73-4B**). It provides simultaneous venous drainage of deoxygenated blood and return of oxygenated blood via the right internal jugular vein. Dual-lumen catheters are designed to minimize recirculation of blood while allowing a patient to remain awake and ambulatory while on ECLS. Use fluoroscopy or transesophageal echocardiography for placement as the return port must be aimed at the tricuspid valve. The insertion technique is identical to the technique described above. The dual-lumen ECMO cannula has limited utility in the Emergency Department due to the precision required for insertion.

ASSESSMENT

Correct placement of venous ECMO cannulas is verified (**Figures 73-2B and 73-6**) with bedside ultrasound, transesophageal echocardiography, fluoroscopy, or radiography.⁴⁰⁻⁴² The distal end of the internal jugular venous cannula should rest at the junction of the superior vena cava and right atrium where it can deliver oxygenated blood to the right atrium. The distal end of the femoral venous cannula should lie in the inferior vena cava below the takeoff of the hepatic veins. Draw and analyze an arterial blood gas (ABG). The ABG goals include a pH of 7.2 or greater, a PaO₂ of 50 mmHg or greater, and a PaCO₂ of 50 mmHg or less. Arterial saturations may approach 80% to 85% depending on the amount of recirculation.¹⁴ This is acceptable for systemic oxygen delivery assuming a normal cardiac output and hemoglobin level.¹⁴

FIGURE 73-6. Drainage cannula positions. Optimal positioning is when the tip of the drainage cannula is in the superior vena cava as noted in parts A-C. **A.** ≥ 2 cm from the right atrium. **B.** ≤ 2 cm from the right atrium. **C.** In the right atrium ≤ 2 cm from the superior vena cava junction. **D.** In the right atrium ≥ 2 cm from the superior vena cava junction. **E.** Against the interatrial septum. **F.** In the inferior vena cava. (Used with permission from reference 40.)

AFTERCARE

Regular monitoring of patient data is essential while on ECMO. Normal hemodynamic values, laboratory data, and initial ECMO settings can be found in **Table 73-4**.⁴³ Titrate the oxygen by adjusting the ECMO flow. Flow is initially set to a maximum of 50 to 80 mL/kg/min and titrated down to maintain pulse oximeter saturations greater than 80% while on the ventilator. This should correlate with an oxygen delivery (DO₂) to consumption (VO₂) ratio of greater than 3 or a mixed venous oxygen saturation (SvO₂) that is 30% lower than a measured arterial oxygen saturation (SaO₂).

Clearance of carbon dioxide (CO₂) is controlled by the sweep gas flow. Blood flow to support oxygenation can cause excessive CO₂ removal if ECMO is initiated for hypoxemia. Titrate the sweep gas flow to maintain a PaCO₂ of 40 mmHg. Blood flow can be maintained at a low level while the sweep gas is titrated up if ECMO is initiated for hypercarbia (e.g., chronic obstructive pulmonary disease or asthma exacerbation).

Recirculation is a phenomenon where freshly oxygenated blood is being shunted from the return cannula to the drainage cannula due to their proximity or malposition. A continuous central venous

TABLE 73-4 Initial Settings for ECMO

Characteristic	Setting or goal
Arterial CO ₂ tension	35–45 mmHg
Arterial O ₂ saturation	V-V ECMO: 85–92% V-A ECMO: > 95%
Circuit flow	50–80 mL/kg/min
FIO ₂	100%
Hematocrit	30–40%
Inlet pressure of centrifugal pump	> 100 mmHg
Mean arterial pressure	65–95 mmHg
Mixed venous O ₂ saturation	> 65%
pH	7.35–7.45
Platelets	> 100,000
O ₂ saturation of drainage cannula	> 65%
O ₂ saturation of return cannula	100%
Sweep gas flow	50–80 mL/kg/min

oxygen saturation (ScvO₂) is provided on most ECMO machines. This is a value measured from the blood in the return cannula as it exits the body. A mixed venous saturation greater than 65% to 70% is acceptable assuming an arterial saturation or hemoglobin saturation in the return cannula of near 100%. It may be an indication that significant recirculation is occurring if the ScvO₂ remains elevated. Correlate this finding with radiographs or ultrasounds of the cannula position. Adjust the cannula position accordingly.

Place the patient on “rest” ventilator settings once stabilized on ECMO. Set the ventilator in pressure control mode with a positive end-expiratory pressure of 5 to 15, an inspiratory pressure of 10, and a respiratory rate of 5. Adjust the fraction of inspired oxygen (FIO₂) to the lowest possible value while still maintaining pulse oximeter saturations greater than 80%. Rest ventilator settings vary by institution.

Provide deep sedation during and immediately after cannulation. Wean the sedation as the patient’s condition improves so that they can breathe spontaneously and ambulate. The patient can assume control of their breathing while sedation is weaned because pressure control ventilation is time-triggered and pressure-triggered. Alternatively, the ventilator mode can be adjusted to provide only continuous positive airway pressure (CPAP) while the patient breathes spontaneously. **Make every effort to liberate a patient from the ventilator while on ECMO.** There may be situations where maintaining the patient on the ventilator in anticipation of ECMO weaning. Extubate the stable patient by ECMO day 5 or consider a tracheostomy.¹⁴ A tracheostomy is an alternative if prolonged respiratory failure is expected.

Initiate all patients on anticoagulation using heparin unless contraindicated. Alternatives to heparin include argatroban and bivalirudin. There is limited data on therapeutic ranges and outcomes using alternative anticoagulation. Heparin can be titrated to achieve anti-Xa, activated partial thromboplastin time (aPTT), or activated clotting time (ACT) goal levels. Some institutions prefer a low-dose heparin protocol during V-V ECMO to reduce the rate of bleeding complications.

Monitor coagulation parameters (e.g., international normalized ratio [INR], partial thromboplastin time [PTT], and fibrinogen), hemoglobin levels, platelet levels, and serum free hemoglobin every 8 to 24 hours to assess the risk of bleeding, clotting, or hemolysis. Normal values will differ between institutions. Acceptable values are generally an INR less than 2, fibrinogen levels greater than 150 mg/dL, hemoglobin levels of 10 g/dL or greater, and platelet levels of 50,000/μL or greater. A serum free hemoglobin of greater than 40 mg/dL may indicate hemolysis. This test is unreliable when hyperbilirubinemia is present. Do not use lactate dehydrogenase as a marker for hemolysis. It is relatively nonspecific and may indicate excessive hemolysis, excessive clotting, or injury to other unrelated organs. Some institutions follow D-dimer levels as markers of clot burden within the membrane oxygenator.⁴⁴

Daily assessments of each membrane oxygenator include visual inspection for clot burden. Clotting within the membrane oxygenator may present as white or red streaks that are typically located on the outskirts of the oxygenator. These should be comprehensively documented so that daily comparisons can be made between multiple teams. Additional oxygenator assessments should include preoxygenator and post-oxygenator ABG measurements. ABG assessment should contain measurements of percent hemoglobin saturation, which can be used to calculate oxygen delivery (DO₂) and oxygen consumption (VO₂). Correlate flow measurement through drainage and return cannulas with the pump RPMs.

Complete a careful assessment of volume status at regular intervals. Observation of the ECMO circuit tubing may alert to hypovolemia within the ECMO circuit. Chugging and chatter are both terms used to describe the rhythmic shaking of the ECMO circuit tubing due to hypovolemia. Volume administration or decreasing pump flows will remedy this problem.

The process of weaning from extracorporeal support is beyond the scope of Emergency Medicine. Assess the ability to wean the patient daily. The primary indication that a patient is likely to wean successfully from ECMO is reversal of the underlying pathology. An example is ARDS. Expect improvement in radiographic findings, improvement in oxygenation and ABG values with minimal ECMO support, larger tidal volumes while breathing spontaneously, and normal hemodynamics without vasopressor support before weaning from ECMO. ECMO discontinuation is a complex process managed by a multidisciplinary team in an inpatient unit.

COMPLICATIONS

Patients are at risk for ECMO-related complications during initiation, maintenance, or discontinuation of extracorporeal support (**Table 73-5**).^{43,45} The complications related to cannulation are like those for the placement of a central venous catheter (Chapter 63). The most common complications include arterial puncture and cannulation, bleeding, cardiac injury, limb ischemia, pneumothorax, and vascular injury. Mechanical complications, including pump thrombus, oxygenator failure, dislodged cannula, or accidental tubing disconnection, occur to lesser degrees.

Patients are at risk for gastrointestinal, intracranial, and catheter-related hemorrhage or thrombosis while ECLS is being maintained. Perform a head computed tomography scan for any acute change in the patient’s mental status or neurologic examination. Check distal arterial pulses at regular intervals to assess for peripheral embolic events. Have a low threshold to check coagulation parameters, especially if the patient is experiencing bleeding. Mechanical circulation can cause an induced von Willebrand factor (vWF) deficiency. Consider a trial of cryoprecipitate, desmopressin, or antifibrinolytic amino acids if patients continue to bleed despite normal platelet levels and coagulation parameters, especially if concomitant renal failure is present.^{46,47}

Infectious complications may occur. These include line-related sepsis, pneumonia, or a urinary tract infection. Some centers

advocate for routine prophylactic antibiotic administration while ECMO cannulas are in place. More data are needed before this becomes standard practice. Rule out an infection before attributing the symptoms to the ECMO circuit.

An infection needs to be determined versus inflammation (**Figure 73-7**).^{48,49} Inflammation is a complication associated with ECMO. This response is similar to the systemic inflammatory response syndrome (SIRS) associated with an infection. The patient's blood in contact with the ECMO circuit results in activation of the complement system and other endogenous systems. This ultimately leads to neutrophil activation, tissue neutrophil infiltration, and organ damage.

ECMO can affect the pharmacokinetics of some medications.⁵⁰ Some medications are sequestered within the ECMO circuit. The volume of distribution is increased with the use of ECMO. This can reduce the concentration of medications by dilution. These can cause subtherapeutic medication levels in the patient's blood. A discussion of the individual drugs is beyond the scope of this chapter and usually managed in the Intensive Care Unit.

SUMMARY

V-V ECMO supports patients with a variety of conditions that lead to acute respiratory failure. Cannulation strategies employed primarily use a combination of femoral and internal jugular vein insertion sites. Understanding aftercare and complications will help the Emergency Physician troubleshoot most problems related to initiation and maintenance of ECMO.

VENO-ARTERIAL ECMO

INDICATIONS

V-A ECMO is indicated in adults, children, and pregnant patients for acute cardiac failure or acute-on-chronic cardiac failure leading to cardiogenic shock (**Figure 73-2B** and **Table 73-6**).^{16,20,21,23,25,28,29,32-34,43,51-74} Acute cardiac failure is caused by conditions in which the heart is abruptly presented with a load that exceeds its capacity to function or when diastolic filling is impaired.

Bridge to cardiac transplant
Bridge to ventricular assist device
Cardiogenic shock, ischemic
Cardiogenic shock, nonischemic
Cardiogenic shock from electrical storm
Cardiomyopathy
Congenital heart disease
Drug overdose
Extracorporeal cardiopulmonary resuscitation (ECPR)
Hyperkalemia
Hypokalemia
Hypothermia
Myocardial depression from sepsis
Myocardial infarction
Myocarditis
Near-drowning
Organ perfusion for donation after cardiac death
Pheochromocytoma circulatory collapse
Poisoning
Support for cardiac catheterization
Support after cardiac surgery
Support after cardiac transplantation
Support perioperatively
Witnessed cardiac arrest from ventricular fibrillation
Witnessed cardiac arrest from ventricular tachycardia

Source: Compiled from references 16, 20, 21, 23, 25, 28, 29, 32–34, 43, and 51–73.

A major advantage to temporary ECLS is the ability of the V-A ECMO circuit to partially offload the myocardium while it recovers. Hemodynamic values that may indicate circulatory support include a cardiac index (CI) below 2 L/min/m², a systolic blood pressure persistently below 90 mmHg despite maximal vasopressor or inotropic support with placement of an intraaortic balloon pump (IABP), or a lactic acidosis related to cardiogenic shock.⁴³

Acute cardiac decompensation can be caused by ischemic or non-ischemic insults to the myocardium. Nonischemic causes of acute cardiac failure include cardiomyopathy (i.e., idiopathic and viral), failure to wean from cardiac bypass (i.e., stunned myocardium), malignant dysrhythmias, pulmonary emboli, or toxic exposures.²⁴

Cardiac arrest due to ischemia after myocardial infarction represents one of the primary indications for ECMO cannulation in the Emergency Department. This is sometimes referred to as extracorporeal cardiopulmonary resuscitation. Nonrandomized studies suggest that use of V-A ECMO in acute myocardial infarction complicated by cardiogenic shock improves in-hospital survival and reduces 30-day mortality when used in conjunction with revascularization.^{75,76}

A bridge to transplantation or bridge to additional mechanical support (e.g., ventricular assist device) are unique indications not commonly encountered in the Emergency Department. A bridge to thrombectomy in pulmonary embolus may be considered in the Emergency Department. Additional indications for V-A ECMO are found in **Table 73-6**.

CONTRAINDICATIONS

Reversible acute heart failure usually requires temporary mechanical support until cardiac recovery occurs. Distinguishing between myocardial stunning and permanent myocardial injury present a major dilemma when considering a patient for temporary ECMO support.

V-A and V-V ECMO share many of the same contraindications. The ability to predict tissue recovery is variable in V-A ECMO, unlike in V-V ECMO. Acute cardiogenic shock and associated comorbid

conditions may argue more heavily against ECMO initiation. An absolute contraindication to V-A ECMO initiation is an underlying disease process that is progressive and irreversible. Other absolute contraindications include permanent neurologic damage, severely depressed functional status, and terminal malignancy.

Acute severe pulmonary arterial hypertension with evidence of right heart dysfunction is not a contraindication to ECLS. V-A ECMO can provide some offloading of the myocardium. This is in contradistinction to V-V ECMO where pulmonary hypertension is a contraindication to cannulation.

The relative contraindications to V-A ECMO differ between institutions. Relative contraindications may exclude a patient from ECLS. These typically include age greater than 75 years old, certain hemoglobinopathies, immunocompromised states, inability to be anticoagulated, multisystem organ failure, and recoverable CNS injury. Obesity can present a technical challenge to ECMO cannulation. The initiation and maintenance of ECMO in obese patients are feasible and safe.³⁹ ECMO can be safely managed without anticoagulation in the short term depending on institution policy.²¹

EQUIPMENT

The equipment required is the same as that for V-V ECMO. The contents of a comprehensive, fully stocked ECMO cart should include supplies for both venous and arterial ECMO. An example of a typical ECMO supply cart can be found in **Table 73-3**. A perfusionist should be available to aid in cannulation and offer troubleshooting advice during initiation and maintenance of ECMO.

PATIENT PREPARATION

The consent, preprocedural data review, patient positioning, and patient preparation are the same as V-V ECMO. Prepare the equipment and ultrasound transducer as discussed previously. Additional risks include arterial dissection, extremity malperfusion, distal embolic event, or life-threatening hemorrhage. Systemically anticoagulate the patient before or after V-A ECMO cannulation. Goal monitoring values of anticoagulation will vary between institutions and should be reviewed prior to administration of anticoagulation.

TECHNIQUE

V-A ECMO initiation can be divided into several phases including patient preparation, access, dilation, cannulation and connection, initiation, and follow-up care. Review any available imaging for variant anatomy or in situ venous thrombus, which may complicate catheter placement. Multiple sites may be cannulated concomitantly, allowing ECMO to be initiated more expeditiously if multiple physicians with expertise in cannulation are present. Venous access for V-A ECMO is identical to that discussed for V-V ECMO.

Some physicians feel that percutaneous cannulation may lead to unnecessary complications due to improper placement. An open femoral artery exposure for cannulation may be performed if the cannulating physician is comfortable with this technique. **Percutaneous femoral artery cannulation remains the quickest and safest method for V-A ECMO cannulation in the Emergency Department and will be discussed below.**

ACCESS

Infiltrate with local anesthetic solution over the proposed access sites. Consider a percutaneous distal perfusion catheter. Place this catheter prior to placement of the larger femoral artery cannula. Do not delay the initiation of ECMO for this catheter. Placement of a perfusion catheter is discussed below under “Special Circumstances.”

Locate the common femoral artery with an ultrasound linear transducer (Chapters 63 and 64). Use the micropuncture needle without an attached syringe to puncture the common femoral artery. The artery must be entered along the anterior wall using a front wall only technique to avoid unnecessary hemorrhage after anticoagulation. The access is the same as described for V-V ECMO.

■ DILATION

Percutaneous dilation of the subcutaneous tract and femoral artery is like that of the vein as described for V-V ECMO.

■ CANNULATION AND CONNECTION

Insertion of the catheter is like that of a venous catheter in V-V ECMO.

■ INITIATION

Connect the venous and arterial access sites to the ECMO circuit. Initiate A-V ECMO.

■ SPECIAL CIRCUMSTANCES

Placement of a percutaneous distal perfusion cannula has the theoretical advantage of avoiding limb malperfusion due to occlusion from the arterial ECMO cannula. This catheter is more easily placed prior to placing the much larger ECMO catheter. Place it into the superficial femoral artery under ultrasound guidance.

ALTERNATE TECHNIQUES

Additional access sites for V-A ECMO support include the axillary artery, central aorta, and innominate artery. These alternate cannulation sites require time-consuming dissections and are rarely performed outside the Operating Room. They are briefly mentioned for completeness. Axillary artery cannulation requires axillary artery exposure below the clavicle. An 8 mm polyethylene terephthalate (i.e., Dacron) graft is circumferentially sutured to a longitudinal opening made through the anterior artery wall once the artery is exposed. This graft is then tunneled laterally in the subcutaneous tissues to be connected to ECMO tubing over the right chest. Aortic and innominate artery cannulation requires the performance of a median sternotomy. The innominate artery is cannulated with a 10 mm Dacron graft sutured to a longitudinal opening in the anterior wall. This can then be tunneled to exit the subcutaneous tissue in the right upper quadrant where it is connected to the ECMO tubing. Aortic cannulation can be accomplished with a tunneled graft conduit or by direct arterial puncture. The chest can remain open and covered with a negative-pressure vacuum system or can be closed.

ASSESSMENT

Verify the correct placement of arterial and venous ECMO cannulas (**Figures 73-2B and 73-6**) with bedside ultrasound, transesophageal echocardiography, fluoroscopy, or radiography.⁴⁰⁻⁴² Arterial cannulas tend to be shorter in length than venous catheters (**Figure 73-8**). They will usually terminate in the common iliac artery or distal aorta. The distal end of the internal jugular venous cannula should rest at the junction of the superior vena cava and right atrium where it can deliver oxygenated blood to the right atrium. The distal end of the femoral venous cannula should lie in the inferior vena cava below the takeoff of the hepatic veins.

AFTERCARE

The aftercare of patients on V-A ECMO is like that of patients on V-V ECMO with minor differences. Key differences include the

FIGURE 73-8. The arterial catheters (red) are shorter than the venous catheters (blue). (Photo courtesy of Maquet Getinge Group, Hechingen, Germany.)

minimal contribution from recirculation, sedation, ventilator management, anticoagulation, and weaning. Patients on V-A ECMO are not at risk for recirculation given the nature of cannula placement. Take systemic, preoxygenator, and postoxygenerator ABG measurements at least daily to assess DO_2 , VO_2 , and recovery of cardiac function.

Sedation is maintained at a moderate level in patients on V-A ECMO. It may be difficult for patients to ambulate or participate in active recovery while on V-A ECMO due to the V-A catheter configuration. Ventilator settings can be minimized, but “lung rest” is not the primary goal in most cases of V-A ECMO. Discuss a tracheostomy with the patient’s surrogate medical decision maker if prolonged intubation is expected.

The location of arterial ECMO cannulas puts the patient at high risk for embolization of blood clots to cerebral, coronary, peripheral, or visceral arteries. Most clinicians prefer anticoagulation strategies targeting higher ACT or aPTT goals. This lessens the risk of embolization but does not eliminate the problem. **Higher anticoagulation goals put patients at risk for hemorrhage.** Perform a thorough pulse and neurologic examination at regular intervals while a patient is on V-A ECMO. Any change should prompt an expeditious work-up.

Myocardial recovery is signaled by improvement in echocardiographic findings. V-V ECMO relies on radiographic improvement and laboratory values to indicate recovering lung function. The liberal use of cardiac echocardiography for V-A ECMO is indicated at least daily.

Stagnant deoxygenated blood ejected by a weak myocardium has little impact on systemic or cerebral oxygenation because the heart is bypassed during V-A ECMO. The heart’s contractility intensifies and causes deoxygenated blood to be ejected more forcefully toward the head vessels and against the flow of the arterial return cannula in the femoral artery as cardiac function recovers.

The merging of mechanical and native circulation is a phenomenon known as a mixing cloud. A patient’s heart could be sending deoxygenated blood into the cerebral circulation causing a neurologic catastrophe without monitoring. Causes of antegrade movement of the mixing cloud include strengthening of myocardial contraction or a reduction in retrograde flow from the arterial return cannula. The mixing cloud will move from the ascending aorta to the aortic arch as the heart recovers. The first vessel to receive deoxygenated blood from the mixing cloud will be the innominate artery. Arterial blood gasses drawn from an arterial cannula placed in the right arm will be the first indication that myocardial contractility is recovering.

A cardiac thrombus can result from stagnant ventricular blood. This is more common in a very weak heart. The stagnation of blood

may occur to varying degrees at any time during A-V ECMO. A thrombus may be found on echocardiography or suspected clinically. Treatment of a ventricular thrombus is aimed at prevention and includes regularly scheduled chest compressions, inotropic support, or placement of an IABP.

Assess the ability to wean from ECLS daily. The primary indication that a patient is likely to wean successfully from ECMO is reversal of the underlying pathology. Expect improvement in echocardiography findings if the underlying cause of the patient's initial instability was reversed. ECMO discontinuation is a complex process managed by a multidisciplinary team in an inpatient unit.

COMPLICATIONS

V-A ECMO-specific complications are discussed in the aftercare section above and include cerebral, visceral, and peripheral embolic events, "mixing cloud" causing cerebral hypoxemia, and cardiac thrombus due to stagnation of bypassed blood. A complete list of complications related to ECMO is found in **Table 73-5**.^{43,45}

SUMMARY

V-A ECMO will provide cardiac and pulmonary support. Cannulation strategies employed in the Emergency Department primarily use a combination of femoral vein and femoral artery insertion sites. Understanding aftercare and complications will help the Emergency Physician troubleshoot most problems related to initiation and maintenance of ECMO.

SUMMARY

ECMO provides temporary cardiopulmonary support for patients presenting to the Emergency Department in extremis. Percutaneous cannulation can be achieved rapidly and is straightforward once arterial and venous access is established. A comprehensive understanding of the care for the ECMO patient will allow the Emergency Physician to successfully navigate many of the acute problems and complications related to ECMO initiation and maintenance.

Catheter-Based Hemorrhage Control

Matthew Rosen and Andrew Grock

INTRODUCTION

Nine percent of the global annual mortality is from trauma.¹ Trauma is the third leading cause of death in the United States for all ages and the leading cause of death in patients 1 to 44 years of age.¹ Hemorrhage is the leading cause of potentially preventable death, is amenable to interventions, and prevention of hemorrhage can reduce morbidity and mortality.^{2,3}

Management of the patient with massive hemorrhage should primarily focus on the basics of resuscitation (i.e., airway, breathing, circulation, obtaining large-bore intravenous [IV] access, and activating massive transfusion protocols). Stopping blood loss is critical to patient survival.⁴⁻⁶ Direct compression at the source of bleeding is usually sufficient. Other options include proximal control with the use of embolization, surgical closure, or tourniquets.^{2,4} Hemorrhage can occur from noncompressible or not readily accessible sites (e.g., gastrointestinal tract, intraabdominal, intrathoracic, pelvic, or

retroperitoneal).⁷ Limited management options exist for hemodynamically unstable patients due to noncompressible hemorrhage. It may prove dangerous to transport these patients to the Endoscopy Suites, Interventional Radiology (IR), or the Operating Room for definitive hemorrhage control.

Aortic occlusion is one hemorrhage control method that temporarily stops noncompressible torso hemorrhage from injuries that receive blood supply from the subdiaphragmatic aorta. Aortic occlusion improves hemostasis, preserves coronary and cerebral perfusion, and can improve hemodynamics enough to allow for definitive hemorrhage control by embolization, endoscopy, or surgical repair.⁸⁻¹⁰ Aortic occlusion may allow more time for induction of anesthesia, intubation, initiation of positive-pressure ventilation, and operative planning.¹¹⁻¹⁶

Emergency Physicians achieved aortic occlusion traditionally through a thoracotomy (Chapter 54) and supradiaphragmatic clamping of the thoracic aorta (Chapter 58).^{17,18} Resuscitative endovascular occlusion of the aorta (REBOA) is a less invasive method of aortic occlusion made possible by advancements in endovascular technology.¹⁷⁻²⁰ Japan has incorporated catheter-based hemorrhage control in the treatment of solid organ and pelvic injuries. The published data from Japan's use of REBOA are limited and largely retrospective. The conclusions based on the Japanese data differ on REBOA safety and effectiveness.²¹⁻²⁴ A systematic review from data obtained in the United Kingdom showed benefits with REBOA utilization in the prehospital setting.²⁵

Success with REBOA has been shown in animal models of intraabdominal, pelvic, and uncontrolled junctional (i.e., buttocks, extremity trauma not amenable to tourniquet use, gluteal, groin, and perineum) hemorrhage.^{9,13,26,27} Case reports and series support its use in hemorrhagic shock from nontraumatic etiologies of bleeding (e.g., during repair of abdominal aortic aneurysm, ectopic pregnancy, massive hemorrhage after hysterectomy, postpartum hemorrhage, and upper gastrointestinal bleeding).^{16,28-32} Clinical studies in trauma patients have shown similar promise for hemorrhage control.^{12,33} The largest prospective trial to evaluate aortic occlusion in the United States for trauma patients showed that REBOA resulted in hemodynamic improvement in 67% of patients and achieved hemodynamic stability for greater than 5 minutes in 47%.³⁴

ANATOMY AND PATHOPHYSIOLOGY

Aortic occlusion results in an increase in the mean arterial pressure (MAP) proximal to the occluded aorta and preserves perfusion to the brain and heart.^{8,10} Metabolic derangements associated with loss of blood flow distal to the balloon can occur. Elevated lactate and other cytokines may have significant effects on patient physiology, especially after balloon deflation.^{10,23} Models are being developed that allow for partial or intermittent occlusion of the aorta. These models aim to obtain a goal MAP proximal to the aortic occlusion while allowing perfusion distally, which may mitigate some of the deleterious effects of prolonged aortic occlusion.^{35,36}

The aorta is separated into three functional zones for the purposes of REBOA (Figure 74-1).³⁷ Aortic zone I is from just distal to the left subclavian artery to immediately proximal to the celiac artery. Aortic zone II is from the celiac artery to the lowest renal artery. Aortic zone III is from just below the lowest renal artery to the iliac bifurcation. Zone I occlusion provides hemostasis from injuries receiving their blood from the celiac plexus, inferior mesenteric artery, superior mesenteric artery, and pelvic vessels (Figure 74-2A). Zone III occlusion provides hemostasis from bleeding pelvic vessels and lower extremity injuries (Figure 74-2B). **Avoid zone II as it has been considered an area where REBOA should be avoided due to the possibility of not occluding bleeding vessels and providing no advantages over zone I occlusion.**¹²

FIGURE 74-1. The functional zones of the aorta.

INDICATIONS

Currently, evidence-based indications for REBOA are poorly defined.³⁸ It can be performed for traumatic arrest from penetrating trauma to the abdomen, lower extremity, or pelvis with less than 15 minutes of cardiopulmonary resuscitation (CPR).^{12,33,34,37,39} Traumatic arrest from blunt trauma with an organized rhythm on the electrocardiogram (ECG) or cardiac activity on focused assessment with sonography for trauma (FAST; Chapter 8) is another indication for REBOA.^{12,33,34,37,39} Perform REBOA in cases of shock from blunt trauma with a positive FAST ultrasound (US) examination or pelvic fracture and without signs of thoracic aortic injury.^{12,24-26,33,34,37,39,40} Shock from penetrating trauma to the abdomen, lower extremity, or pelvis is another indication for REBOA.^{12,33,34,37,39} Patients with severe hemorrhage from nontraumatic sites are candidates for REBOA if the hemorrhage source receives its supply from the subdiaphragmatic aorta.^{14-16,23,28,30-32} A proposed algorithm for the utility of REBOA in patients in hemorrhagic shock is shown in Figure 74-3.^{19,33,37} REBOA is being proposed and studied for cardiac arrest unrelated to trauma or hemorrhage.⁴¹

REBOA may be advantageous for patients who are partial responders or nonresponders to resuscitation. It can be performed at the bedside in the Emergency Department without the risks associated with patient transport. Consider early femoral artery access in patients at high risk of developing hemorrhagic shock (Chapter 72). Obtaining arterial access is difficult in hypotensive patients or after cardiopulmonary arrest. A femoral arterial line is quickly converted to an appropriate sheath for the REBOA procedure. Perform REBOA in institutions where Interventional Radiologists, Surgeons, and staff are familiar with REBOA catheters including their inflation, deflation, and removal. Emergency Physicians in Japan perform REBOA frequently and proficiency as REBOA placement is a requirement for board certification.⁴²

CONTRAINDICATIONS

Obtain chest radiography to examine the thoracic aorta prior to REBOA placement because the resulting increase in proximal MAP from REBOA could worsen a thoracic aortic injury. Use caution in patients with peripheral vascular disease or prior femoral artery procedures as their anatomy may be more challenging and increase the risk of complications.

FIGURE 74-2. Examples of balloon catheter occlusion. **A.** Zone I. **B.** Zone III. (Photos courtesy of Simbionix, Israel.)

EQUIPMENT

There are several REBOA catheters, arterial access kits, and wires used for vascular procedures. The most commonly used current REBOA catheter is the Coda catheter (Cook Medical, Bloomington, IN) (**Figure 74-4**). There are radiopaque markers at the distal and proximal ends of the balloon. There are two ports, one for the balloon inflation/deflation and the other for guidewire placement.

Performing REBOA with the Coda catheter or other catheters that require guidewires and larger femoral sheaths will be termed *traditional REBOA* in this chapter.³⁷ The ER-REBOA catheter (Prytime Medical, Lakewood, CO) does not require a long guidewire for catheter placement and uses a 7 French femoral sheath for catheter placement (**Figure 74-5**).⁴³ The orange sheath is used to straighten the nontraumatic P-tip for insertion into the sheath. The P-tip allows the ER-REBOA to be placed without a guidewire

unlike other REBOA catheters. There are two ports, one for balloon inflation/deflation and a proximal arterial line port for monitoring pressures in the aorta proximal to the occlusion. The list of recommended supplies for performing traditional REBOA, a comparison of current REBOA catheters, and the equipment needed for using ER-REBOA are listed in **Tables 74-1 through 74-3**.

Fluoroscopy can aid in REBOA catheter placement by confirming central aortic wire placement, balloon catheter location, and balloon inflation.⁴⁴ Fluoroscopy may not be readily available in some institutions in emergent situations. Other methods to safely and accurately place REBOA catheters have been researched (e.g., external landmarks, morphometric roadmap equations to determine measurements from the femoral artery to major aortic branch points, and torso length).⁴⁵⁻⁴⁷ US and contrast-enhanced US have shown promise in confirming wire placement and balloon positioning.^{48,49}

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative if time and patient hemodynamics allow. Obtain an informed consent for the procedure, and place this in the medical record. Document the reason for not having a consent in the record if there is no time for it to occur. The patient should already be in the supine position. Place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them during and after the procedure.

Prepare for the procedure. Identify the femoral arterial pulse by palpation or US. Clean the groin area of any blood, debris, and

dirt. Apply chlorohexidine or povidone iodine to the area and let it dry. **Maintain sterility from this point forward.** Don full personal protective equipment (i.e., hat, mask, sterile gloves, and sterile gown). This protects the Emergency Physician from exposure to the patient's blood and the patient from iatrogenic infections. Apply full sterile drapes onto the patient. Instruct the nurse to administer prophylactic IV antibiotics.

Prepare the US transducer if using US with the procedure. Have an assistant apply US gel over the footprint of the transducer. Instruct the assistant to place the gel-coated US transducer in the sterile cover while you hold it. Have the assistant place sterile US gel over the transducer or the patient. Reidentify the femoral artery pulse. Apply a 25 gauge needle onto a 10 mL syringe. Fill the syringe with local anesthetic solution. Inject local anesthetic solution subcutaneously and over the femoral pulse.

TECHNIQUES

New techniques and equipment are currently being developed.²⁰ The basic steps to performing REBOA include obtaining arterial access, positioning an appropriate catheter, and inflating the balloon. The above steps are all that is required of the Emergency Physician. Further steps in management will be described briefly as they take place after hemorrhage control with the patient in the care of the inpatient team. Two techniques for performing REBOA will be described, the traditional approach with catheters that require a guidewire for placement and aortic occlusion using the ER-REBOA catheter.

TRADITIONAL REBOA

Obtain femoral access with an introducer needle by using the anatomic landmarks (Chapter 72), a femoral cutdown (Chapter 69), or US guidance (Chapter 64). The approach using anatomic landmarks involves palpating for the femoral pulse and aiming 1 to 2 cm inferior to the inguinal ligament. Identifying the femoral artery may be challenging in hypotensive patients without palpable pulses. The Emergency Physician should have experience using a femoral artery cutdown if it is to be performed. **Observe several cardinal rules for the insertion of the catheter. Always occlude the open hub of a catheter, needle, or sheath to prevent an air embolism. Never let go of the guidewire to prevent its embolization into the circulation. Never apply excessive force to the guidewire on insertion or removal. Doing so may injure the vessel, break the guidewire, and/or embolize the guidewire.**

Attach the introducer needle to a 5 mL syringe containing 1 mL of sterile saline or local anesthetic solution. The specially designed introducer needle included with the catheter should be used, as it has a relatively thin wall and a larger internal diameter relative to its external diameter. It has a shorter bevel than a conventional hypodermic needle. It has a tapered hub to guide the guidewire into the needle proper.

If there is doubt about the exact location of the femoral artery, it may first be located with a small “finder” needle. Insert a 25 or 27 gauge needle attached to a 5 mL syringe through the skin puncture site previously chosen. Advance the needle at a 30° to 60° angle to the skin while applying negative pressure to the syringe. A flash of blood signifies that the tip of the needle is within the artery. Note the depth and location of the artery. Remove the finder needle. Alternatively, the finder needle may be left in place for reference.

Insert the introducer needle at a 30° to 60° angle. Inject a small amount of the fluid in the syringe to remove any skin plug that may block blood return once the artery has been penetrated. Apply negative pressure to the syringe by withdrawing the plunger. Advance the introducer needle into the artery (**Figure 63-10A**). The artery's distance will vary depending on the patient's size and the target vessel's location. Stop advancing the introducer needle if the artery is not located within 3 to 5 cm of the skin. Withdraw the needle slowly while continuing to aspirate. The vessel will often have been completely traversed. If no blood is aspirated while withdrawing the needle, withdraw the introducer needle to the subcutaneous plane and redirect it. Avoid putting continuous pressure on the femoral artery pulse as even gentle pressure may collapse it.

Stabilize and hold the introducer needle perfectly still with the nondominant hand once blood returns in the syringe. The femoral artery has been entered if the blood is bright red and/or forces the plunger of the syringe back. Remove the syringe. **Blood should pulsatile flow freely from the hub of the needle.** Occlude the open

hub of the introducer needle with the thumb of the nondominant hand while keeping the small finger of the hand in contact with the patient's skin. The Emergency Physician's proprioceptive reflexes will prevent movement of the introducer needle by maintaining contact with the patient's skin. Even a millimeter of movement may result in failure to stay within the lumen of the artery.

Prepare the guidewire (**Figure 63-11**). Grasp the guidewire and its sleeve with the dominant hand. The tip of the guidewire has a “J” shape when the sleeve is retracted (**Figure 63-11A**). Slide the sleeve forward to straighten out the “J” of the guidewire (**Figure 63-11B**). Insert the guidewire sleeve into the hub of the introducer needle (**Figures 63-10B and 63-11C**). Advance the guidewire through the sleeve and into the introducer needle. **Never let go of the guidewire. One end of the guidewire must always be held to prevent its loss and embolization.**

Do not simply reverse the guidewire if the sleeve used to straighten the curved end of the guidewire is lost. The straight end of the guidewire can puncture the wall of the artery. Grasp the guidewire between the fourth and fifth fingers and the palm of the dominant hand (**Figure 63-12A**). Apply gentle traction on the curved guidewire tip with the thumb and the second fingers to straighten the guidewire (**Figure 63-12B**). The guidewire can then be inserted into the introducer needle hub without the use of the sleeve.

Advance the guidewire through the introducer needle and into the artery (**Figure 63-10B**). The guidewire should advance easily into the artery. **Never force the guidewire.** Guidewire resistance may indicate that the introducer needle is not within the artery, is against the wall of a vessel, or is caught as the vessel bends. Slightly withdraw the guidewire, rotate it slightly, and readvance it. **The use of force will kink the guidewire and may cause it to damage the artery and adjoining tissues.** Advance the guidewire into the vessel. US can confirm the appropriate position of the guidewire in the femoral artery (**Figure 74-6A**). Withdraw the introducer

FIGURE 74-6. US images of the guidewire and catheter. **A.** Longitudinal view of the guidewire within aortic zone III. **B.** Longitudinal view of the Coda catheter tip and inflated balloon with microbubbles within aortic zone III. **C.** Sagittal view of the Coda catheter tip and inflated balloon with microbubbles within aortic zone III. **D.** Longitudinal view of contrast-enhanced US of balloon inflated with microbubbles and air within the aorta. (Used with permission from reference 48.)

needle and guidewire sheath while securely holding the guidewire (**Figure 63-10C**). Grasp the guidewire with the nondominant hand as soon as the guidewire is visible between the tip of the introducer needle and the skin. Finish removing the needle over the guidewire.

Make a small incision in the skin adjacent to the guidewire using a #11 scalpel blade (**Figure 63-10D**) to allow for passage of serial dilators. Place the dilator over the straight end of the guidewire (**Figure 63-10E**). Advance the dilator over the guidewire, through the skin, and into the artery. A slight twisting motion of the dilator as it is advanced may aid in its insertion. Continue to advance the dilator until its hub is against the skin. **Do not release hold of the guidewire at any time.** Remove the dilator over the guidewire. Continue to apply the next size dilator, advance it, and then remove the dilator until the appropriate size is used.

Place the sheath tip over the guidewire. Advance the sheath over the guidewire and into the artery (**Figure 63-10F**). **Do not release hold of the guidewire.** Gently rolling or twisting the sheath between the thumb and forefinger may aid in its advancement. Insert the sheath to the predetermined desired depth. Hold the sheath securely in place and remove the guidewire (**Figure 63-10G**). **Occlude the open sheath lumen with a sterile-gloved finger to prevent an air embolism and excessive blood loss.** Ensure the stopcock on the sheath is in the off position or pointing toward the patient to avoid blood loss.

Determine the REBOA catheter length based on which zone of occlusion is indicated. Zone I occlusion requires a longer (i.e., 45 to 65 cm) sheath to maintain the balloon in appropriate position against the pulsatile forces in the proximal aorta. Zone III occlusion can be performed using the shorter introducer sheath (i.e., 10 to 25 cm) as the bifurcation of the aorta will firmly hold the inflated balloon in place.

The introducer sheath needs to be exchanged for the longer sheath to maintain the position of the inflated balloon for zone I occlusion. Advance a 0.035 inch wire until the floppy tip is in the distal aortic arch. Fluoroscopy is the best method to confirm proper placement. The distance from the femoral head to a point halfway between the xiphoid process and the medial clavicular head can be used as an estimated length of insertion if fluoroscopy is unavailable. The

subxiphoid FAST view on US can be used to demonstrate central aortic wire placement.⁴⁹ Remove the short introducer sheath when the wire is placed. **Ensure the wire remains stationary by holding it against the patient as the sheath is removed.** The longer sheath is advanced over the wire to the desired location.

Apply the balloon catheter over the wire. Advance the balloon catheter through the sheath. Confirm appropriate balloon placement with fluoroscopy or US (**Figure 74-7B**). If unavailable, the balloon can be advanced 5 cm longer than the sheath prior to balloon inflation. Inflate the balloon with a 30 to 60 mL syringe filled with half-saline and half-saline with iodinated contrast (**Figure 74-7C**). Use fluoroscopy to adjust the balloon inflation so that the outer edges are parallel (**Figure 74-8**).^{27,50} Other methods to determine adequate inflation include loss of distal pulses (e.g., especially the contralateral femoral pulse) and increased blood pressures proximal to the balloon measured with a proximal arterial line. US may be used to confirm catheter placement and balloon inflation with microbubble contrast (**Figures 74-6B through 74-6D**).^{48,51} Turn the three-way stopcock when the balloon inflation appears adequate. Turn the stopcock toward the balloon port or patient to maintain balloon inflation and occlusion. Note the volume instilled into the balloon and place this in the medical record.

Securing the balloon, sheath, and wire apparatus in the appropriate position is often best achieved by an assistant. There is the tendency of the REBOA catheter to migrate. Use an assistant who can identify and communicate position changes. This is preferable to suturing, taping, or using securing clips to secure the apparatus.

ER-REBOA

ER-REBOA requires only a 7 French introducer sheath, does not require a long guidewire, does not require fluoroscopy for placement, and comes with a proximal arterial line monitoring port (**Figure 74-5A**). Obtaining femoral access is the same as the traditional REBOA procedure with the goal of inserting a 7 French introducer sheath.

FIGURE 74-7. Insertion of the catheter. **A.** The arterial system. **B.** Insertion of the REBOA catheter. **C.** Inflation of the REBOA catheter balloon. (Courtesy of Prytime Medical, Boerne, TX.)

FIGURE 74-8. Inflated REBOA catheter in zone I. **A.** The catheter is conforming to the shape of the aorta. (Photo used with permission of reference 27.) **B.** The ER-REBOA balloon inflated with saline. (Photo used with permission of reference 50.)

Attach a 30 mL syringe filled with 24 mL of normal saline to the balloon port of the ER-REBOA catheter. An alternative is to attach a syringe containing a mixture of contrast and saline. Ensure the balloon functions and has no leaks by inflation and deflation. **Lock the stopcock after deflating the balloon to prevent an air embolism.** Attach a pressure transducer to the arterial line port of the catheter and zero the transducer (Chapter 72).

Measure to the zone of desired occlusion using external landmarks. Zone I is measured with the proximal edge of the balloon or closest portion to the catheter ports (**Figure 74-5**) at the edge of the xiphoid. Zone III is measured with the proximal edge at the umbilicus. A long introducer sheath for zone I occlusion is not needed as in the traditional approach.

Straighten the P-tip with the orange sheath. Insert the orange sheath into the femoral introducer sheath (**Figure 74-5B**). Advance the ER-REBOA catheter a few centimeters into the introducer sheath. Pull the orange sheath back. Advance the ER-REBOA catheter to the predetermined depth. Catheter placement may be visualized using US or fluoroscopy to identify the catheter in the central aorta as is done with traditional REBOA.

Hold the ER-REBOA catheter in place. Inflate the balloon until moderate resistance is felt or the arterial line transducer shows an increase in blood pressure proximal to the balloon. It usually takes between 12 and 22 mL of saline depending on the size of the patient's aorta. **Instilling more than 24 mL can lead to device failure or aortic injury.** Turn the stopcock toward the balloon port or patient to maintain balloon inflation and occlusion. Note the volume instilled into the balloon and place this in the medical record.

Securing the balloon, sheath, and wire apparatus in the appropriate position is often best achieved by an assistant. There is the tendency of the ER-REBOA catheter to migrate. Use an assistant who can identify and communicate position changes. This is preferable to suturing, taping, or using securing clips to secure the apparatus.

PEDIATRIC CONSIDERATIONS

REBOA may eventually be an adjunct in the management of the pediatric patient with life-threatening hemorrhage.⁵² Studies have yet to assess age-related vascular diameter changes, anatomic considerations, consistency of landmark identification, safety, and feasibility. It can be used in large adolescents like they are small stature adults.

AFTERCARE

The next step is definitive hemorrhage control with the balloon inflated. The remaining steps are beyond the scope of the Emergency Physician. It may be helpful to understand the basics of REBOA catheter removal. The assistant maintains the position of the balloon apparatus. The Surgeon deflates the balloon. Note the volume retrieved during deflation and compare this to the initial inflation volume. Deflation of the balloon in cases of prolonged inflation or incomplete resuscitation may lead to washout of metabolic byproducts, acidosis, and hypotension. Intermittent balloon deflation and inflation may be necessary until stability is maintained. Limit the amount of distal hypoperfusion from the REBOA catheter to minimize ischemic time and the consequences of inflammatory-mediated organ failure after REBOA.^{23,53}

Remove the deflated balloon when REBOA is no longer necessary. Flush the sheath with 100 mL of heparinized saline made with 1000 units of heparin in 1 L of saline. Sheaths up to an 8 French can be removed safely with manual pressure or with a closure device to control bleeding from the arteriotomy site.⁵⁴ Catheters used for traditional REBOA are larger and will require femoral exposure and closure.

COMPLICATIONS

There are potential complications associated with performing a REBOA. Damage to the femoral vasculature during initial arterial access can occur. There are reports of external iliac artery injury and lower limb ischemia requiring lower limb amputation.²² The long

wires used with the traditional REBOA have the potential to result in injury to cerebral vessels or coronary vessels or induce cardiac arrhythmias if inserted too far.³⁷ The inflated balloon can cause bowel ischemia and limb ischemia.⁵⁵ Other potential complications include vascular damage from balloon inflation in a nontarget vessel (e.g., iliac arteries and renal artery) or balloon overinflation. Paralysis secondary to spinal cord ischemia is a theoretical possibility. Thrombotic events can occur due to aorta occlusion, loss of distal blood flow, or the presence of a foreign body in the vascular system. Perform frequent neurovascular checks and angiographic imaging when indicated. Prolonged occlusion time may lead to severe lactic acidosis, metabolic derangements, and increased inflammatory markers. The combination of these effects may precipitate multi-system organ failure when the balloon is deflated and perfusion is restored.^{22,39,53} The complications are decreased using smaller diameter 7 French sheaths.⁵⁶ In one trial of 46 patients, 4% developed a distal embolism and 2% developed pseudoaneurysms.³⁴ There were no amputations, extremity ischemia, fistulas, hematomas, infections requiring antibiotics, or cases of paralysis.³⁴

SUMMARY

REBOA is a potentially lifesaving technique if performed in the appropriate patient. REBOA catheters can be placed to obtain aortic control in patients with hemorrhagic shock or may be placed prophylactically in patients at risk of developing hemorrhagic shock secondary to injuries with blood supplied by the subdiaphragmatic aorta. REBOA serves as a less morbid alternative to a thoracotomy for patients with life-threatening and noncompressible torso hemorrhage. The procedure can be broken down into the basic steps of obtaining arterial access, selecting a balloon occlusion catheter, placing the catheter, inflating the balloon, and eventually deflating and removing the catheter. The resuscitative environment must be conducive to the use of REBOA, and resources for timely definitive hemorrhage control must be available.

Nasogastric Intubation

Alex Koo and Ryan Walsh

INTRODUCTION

Nasogastric (NG) intubation is a commonly performed procedure in the Emergency Department.¹ Its use as a conduit into the stomach was first popularized in the early twentieth century mainly through the efforts of Dr. Levin. Clinicians have since studied its use, proposed methods to improve the ease with which the NG tube is inserted, and determined ways to diminish the incidence of potentially lethal complications. A NG tube is often placed in patients who have a bowel obstruction, intoxication, intractable nausea and vomiting, significant trauma, or upper gastrointestinal (GI) bleeding or who are endotracheally intubated. The procedure is rapid, simple, and straightforward. The insertion of an NG tube is slowly decreasing.²⁻⁷

ANATOMY AND PATHOPHYSIOLOGY

The nasal cavity is lined by the very vascular nasal mucosa. The medial wall of the nasal cavity is composed of the septum. The lateral wall of the nasal cavity is covered by the turbinates or concha. The posterior nasal cavities are continuous with the nasopharynx that develops into the posterior oropharynx caudally (**Figure 75-1**). The oropharynx continues inferiorly as the esophagus that travels through the esophageal hiatus in the diaphragm and enters the stomach.⁸

FIGURE 75-1. Basic anatomy of the path of the NG tube.

Pediatric nasopharyngeal anatomy differs from that of adults and can result in a more difficult NG tube insertion. The nostrils and nasal passages of children are quite small and limit the size of NG tube that may be passed. Children have relatively large tonsils and adenoids, which may hinder passage of the tube. The nasal tissues are often soft, easily injured, and may bleed as the NG tube is passed. The tongue is large by comparison with adults and may push into the oropharynx and impede passage of the NG tube.

INDICATIONS

NG intubation may be performed for diagnostic or therapeutic indications.² **The primary indication for NG intubation is gastric decompression.** This may help relieve a bowel obstruction, volvulus, or recurrent vomiting (e.g., pancreatitis). NG tubes are placed to decompress the stomach preoperatively, postintubation, or prior to a procedure (e.g., diagnostic peritoneal lavage or pericardiocentesis).

An NG tube may be placed for diagnostic purposes. A diagnostic indication for NG tube placement is to aspirate stomach contents to evaluate the presence, rapidity, and volume of an upper GI hemorrhage. The detection of an upper GI bleed may be unreliable via this technique.⁴ Do not use the fecal Hemoccult card on gastric aspirates to test for occult blood in gastric aspirates. A Hemoccult card may be inaccurate due to gastric aspirate acidity. The Gastroccult card uses a developer that neutralizes gastric acid and renders it able to detect hemoglobin.^{9,10} An NG tube may be inserted to instill air into the stomach to assess for an intraperitoneal perforation. Gastric fluid and contents may be aspirated for laboratory analysis. NG tubes may be placed to visualize the anatomy of the proximal GI tract on a radiograph. An NG tube demonstrates a diaphragmatic hernia or a blind esophageal pouch in children on chest radiography with coiling visualized superior to the diaphragm.

An NG tube can be used for administration of medications, oral contrast for diagnostic studies, nutrition, and gastric lavage. NG tubes are an effective and inexpensive means of hydration.¹¹⁻¹⁴

CONTRAINDICATIONS

Absolute contraindications do not exist for NG tube placement. The relative contraindications are geared toward predicting which patients are more likely to experience complications and which patients are likely to have misplaced tubes. Avoid insertion of an NG tube unless necessary in the patient with midface trauma or a suspected basilar skull fracture. Intubation through the nasal cavity in these patients can result in the NG tube being misdirected through a perforation in the cribriform plate of the ethmoid bone and into the brain. Patients with facial trauma or basilar skull fractures are best served with orogastric tubes.¹⁵

Relative contraindications include coagulopathies, esophageal strictures, ingestions of alkaline substances, nasal obstruction, or recent nasal or gastric surgery. Patients with esophageal varices pose a relative contraindication. Placement of a semirigid tube into the esophagus or stomach has the potential to cause rupture of the varices and uncontrollable hemorrhage. NG placement is generally considered safe in these patients if done carefully.^{16,17} Talk to

the Surgeon before putting an NG tube in any patient with stomach surgery (i.e., recently or in the past). The tube can perforate the proximal pouch and may not decompress the stomach.

EQUIPMENT

- Topical anesthetic (e.g., benzocaine spray, cocaine, viscous lidocaine)
- Topical vasoconstrictor (e.g., phenylephrine, oxymetazoline, cocaine)
- 2% or 4% lidocaine for nebulization
- Glass of water with straw
- Emesis basin
- Water-based lubricant
- NG tube, various sizes
- 60 mL syringe
- Wall suction, set to low intermittent suction
- Suction tubing
- Benzoin
- 1 inch adhesive tape
- Tongue depressor

NG tubes are made of clear polypropylene. They are semirigid and single-use devices. The two most commonly used NG tubes are the Levin tube (**Figure 75-2A**) and the Salem Sump tube (**Figure 75-2B**). They both have multiple distal sideports for aspiration. The Levin tube is a single-lumen tube that is easy to insert (**Figure 75-2A**). It is simple to use for the aspiration of gastric contents, the instillation of fluids and/or medications, and the application of low intermittent suction. The tube has a radiopaque stripe. The amount of suction is difficult to control with the Levin tube. The distal sideports can become occluded with the gastric mucosa and damage this tissue when the tube is attached to suction. The Salem Sump tube is a double-lumen, radiopaque tube (**Figure 75-2B**). It has a smaller suction lumen than the Levin tube. The second lumen allows a constant inward airflow to prevent the sideports from becoming occluded by the gastric mucosa.

PATIENT PREPARATION

The most beneficial factor in the successful placement of a NG tube is a patient who is informed of the procedure and can cooperate with the instructions. Explain the risks, benefits, and complications associated with the procedure to the patient and/or their representative. Take the patient through each step prior to the start of the procedure to ensure maximal cooperation. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Place the patient seated upright. Examine the patient for nasal septal deviation or other anatomic abnormalities that may hinder the passage of the NG tube. Ask the patient to breathe through one nostril while the other nostril is occluded to determine which nostril is the most patent.¹⁸ Drape the patient to protect them and the bedding from soilage if there is emesis. Have a glass of water and a straw within the patient's reach if not contraindicated. Have an emesis basin within reach of the patient.

Consider the use of anesthesia to make the procedure more tolerable (Chapter 205).^{19,20} The application of topical lidocaine and phenylephrine to the nose and benzocaine spray to the throat resulted in significantly less pain and discomfort than the use of

A

B

FIGURE 75-2. Common types of NG tubes placed in the Emergency Department. **A.** Levin tube. **B.** Salem Sump tube.

lubricant alone.²¹ A sample protocol would include the instillation of 0.5% phenylephrine nasal spray followed by viscous lidocaine. Cetacaine spray can be used to anesthetize the nose and the throat.¹⁸ Nebulized 4% lidocaine (e.g., 2.5 mL of saline containing 100 mg of lidocaine) via facemask can be used in adolescents and adults.¹⁹ It has been shown to be superior to lidocaine spray as an anesthetic to reduce gagging and vomiting while increasing the success of NG tube placement.²²⁻²⁴ The dose used in children has been 4 mg/kg of lidocaine for nebulization of a 2% or 4% lidocaine solution.²⁵ **Be cautious when calculating the proper weight-based doses and volume of solution for children.** Lidocaine can also be administered in the nasal cavity, nasopharynx, and oropharynx using a mucosal atomizer device (**Figure 29-1** and **Table 29-1**). A small pilot study demonstrated that the administration of 2 mg of intravenous midazolam with cophenylcaine (i.e., lidocaine 5% with 0.5% phenylephrine) was more effective in controlling pain during NG tube insertion than cophenylcaine alone.²⁶ Lidocaine gel can be inserted in the nasal cavity.²⁷ Allow 3 to 5 minutes for these medications to take full effect before inserting the NG tube.

Choose a size of NG tube that is appropriate for the patient. A size 16 to 18 French is typically used for an adolescent or adult patient. A formula (e.g., [age in years + 16] ÷ 2) may be used to choose the proper size NG tube for children. Other less commonly used methods are available to determine the proper size NG tube in children.²⁸⁻³⁰ This includes two times the endotracheal tube length

FIGURE 75-3. Determining the proper length of NG tube to insert. **A.** The length is determined by the distance from the xiphoid process to the tip of the nose to the earlobe. **B.** The length is determined by the distance from the tip of the nose or lip to around the left ear and to just below the left costal margin. A piece of tape should be used to mark the distance on the NG tube.

formulas. Typical sizes include 8 French for infants, 10 to 12 French for small children, and 12 to 14 French for older children.

Estimate the length of the NG tube to be inserted (**Figure 75-3**). Place the tip of the NG tube on the patient's xiphoid process and extend it to the tip of the nose and over the earlobe (**Figure 75-3A**). Measure this distance and add 15 cm or 6 inches. Mark this distance with a piece of tape on the NG tube. Alternatively, place the tip of the NG tube on the tip of the nose or lip and extend it over the left ear and to just below the left costal margin (**Figure 75-3B**). Mark this distance with a piece of tape.¹⁸ Some use a formula in children of orogastric length = $[3 \times \text{weight (kg)} + 12 \text{ cm}]$ or nasogastric length = $[3 \times \text{weight (kg)} + 13 \text{ cm}]$.

TECHNIQUE

Administer the appropriate anesthetics, antiemetics, or anxiolytics.³¹ Lubricate the first 4 inches or 10 cm of the NG tube with water-soluble lubricant. Position the patient. Place their neck in slight flexion. Gently introduce the NG tube along the floor of the nostril and under the inferior turbinate (**Figure 75-4A**). Advance the NG tube parallel to the nasal floor until it reaches the nasopharynx as indicated by mild resistance (**Figure 75-4A**). **Do not insert and advance the NG tube in an upward or lateral direction to prevent**

impingement and damage to the turbinates. Instruct the patient to swallow. This may be assisted by having the patient sip water through a straw if not contraindicated. Continue to advance the NG tube (**Figure 75-4B**). Advancement may be aided by rotating the NG tube medially. **Withdraw the NG tube if at any time significant resistance to advancement, respiratory distress, the inability to speak, or significant nasal hemorrhage occurs.**¹⁸ Advance the NG tube until the distance previously measured with the tape is at the nostril (**Figure 75-5**). Verify proper placement (**Figures 75-6, 75-7, and 75-8**).

ALTERNATIVE TECHNIQUES

The NG tube may coil in the oropharynx, mouth, or hypopharynx (**Figure 75-6C**). A larger bore NG tube may be used and may not coil. Cool the NG tube in cold tap water or ice water for 5 minutes to make the tube stiffer and then reinsert it. An alternative is to place the distal end of an NG tube into an oropharyngeal airway and then chill it in ice water (**Figure 75-9**). The oropharyngeal airway will place a curve in the chilled NG tube, which may allow it to pass easier. The chilled NG tube will retain this curve for 30 to 60 seconds until it rewarms (**Figure 75-9**). Another alternative is to turn the patient's head laterally if not contraindicated.³²

One study attempted to improve the success rate of NG tube placement by providing external and medially directed pressure on the ipsilateral neck at the level of the thyrohyoid membrane.³³ This maneuver will collapse the piriform sinus and eliminate it as a potential site for impaction. This maneuver was successful for difficult NG intubation in 85% of patients.

There is a greater chance of tube misplacement in the intubated or unconscious patient due to difficulty with cooperativity and positioning. An option is to place several fingers through the patient's mouth and into the oropharynx. The fingers can be used to guide the NG tube against the posterior oropharyngeal wall and into the hypopharynx without it coiling. **Reserve the finger technique for intubated patients in whom the gag reflex is not a concern. Do not attempt this unless the patient is unconscious or paralyzed to prevent them from biting and injuring the fingers.** Use a tongue depressor to move the tongue to the floor of the mouth and make manipulation of the NG tube easier by creating more space in the mouth to maneuver.

Another technique to help pass an NG tube involves direct visualization using a direct or video laryngoscope and an airway forceps (e.g., Boedeker, Magill, or Tylke).^{34,35} Insert the NG tube through the nose and advance it into the oropharynx or hypopharynx. Insert the laryngoscope blade and visualize the distal tip of the NG tube and the esophageal opening. Grasp the tip of the NG tube with the forceps and advance it into the esophagus. Continue to advance the NG tube until the tip is within the stomach. Feed a gum elastic bougie through the distal NG tube eyelet to give it more rigidity for initial insertion.³⁶ This technique can be used on the unconscious and intubated patient when the NG tube will not pass into the esophagus.

The NG tube may easily pass the hypopharynx but not pass completely through the esophagus and into the stomach. **The tip of the tube may be caught at the level of the cricopharyngeus muscle, behind the left mainstem bronchus, or at the lower esophageal sphincter.** Attempt to pass an NG tube that has been cooled for 3 to 5 minutes in cold tap water or ice water. Grasp the thyroid cartilage and lift it anterior and upward to open the esophagus and allow passage of the NG tube through the upper esophagus.

An orotracheally intubated patient requires an NG tube to decompress the stomach, which can be achieved via a modified Seldinger technique.³⁷ Remove the respiratory adapter from the proximal end of a second endotracheal tube. Liberally lubricate the endotracheal tube and insert it through the patient's mouth and into

FIGURE 75-4. Insertion of the NG tube. **A.** The NG tube is inserted parallel to the floor of the nasal cavity and at a 90° angle to the philtrum. **B.** The NG tube is advanced along the floor of the nasal cavity, through the nasopharynx and oropharynx, and into the esophagus. It is further advanced until the tape mark is at the philtrum.

FIGURE 75-5. Proper placement of the NG tube. The tip of the tube resides within the stomach. To confirm proper placement, inject air through the NG tube while simultaneously auscultating over the stomach.

the esophagus. Insert a well-lubricated NG tube through the endotracheal tube and into the stomach. Confirm the proper position of the NG tube. Carefully withdraw the endotracheal tube over the NG tube. Reconfirm that the distal end of the NG tube remains within the stomach.

The risk for tube misplacement is greater in the intubated patient who is unable to assist with NG intubation. Ensure that the NG tube does not come out of the patient's mouth and that there are no changes in the patient's oxygen saturation when inserting the NG tube (**Figures 75-6D and 75-6E**). It is very easy for the NG tube to pass by the cuff of an endotracheal tube without much resistance.³³ **It is paramount that correct placement of the NG tube is verified clinically and radiographically before it is used to instill any fluid or medication.**

ASSESSMENT

Verify proper placement by aspirating stomach contents, auscultating a rush of air over the stomach while 20 to 30 mL of air is insufflated using a syringe through the NG tube, and/or by radiographically demonstrating the tip of the NG tube in the stomach and below the diaphragm (**Figures 75-6, 75-7, and 75-8**).³⁸⁻⁴⁰ **Infusion of substances through a misplaced NG tube could be disastrous.**

Verify the position of the NG tube with simple techniques.³⁸⁻⁴⁰ The patient should be able to speak without respiratory distress immediately after placement of the NG tube. Observe the patient for complaints of drooling, dysphagia, fever, mediastinal air, neck pain, substernal chest pain, subcutaneous air, or trismus. These are signs of esophageal perforation or NG tube misplacement.^{41,42} Air insufflated into the pleural space or the esophagus after misplacement of the NG tube can be just as easily heard over the upper abdomen.¹¹ Gastric contents should be able to be aspirated through the

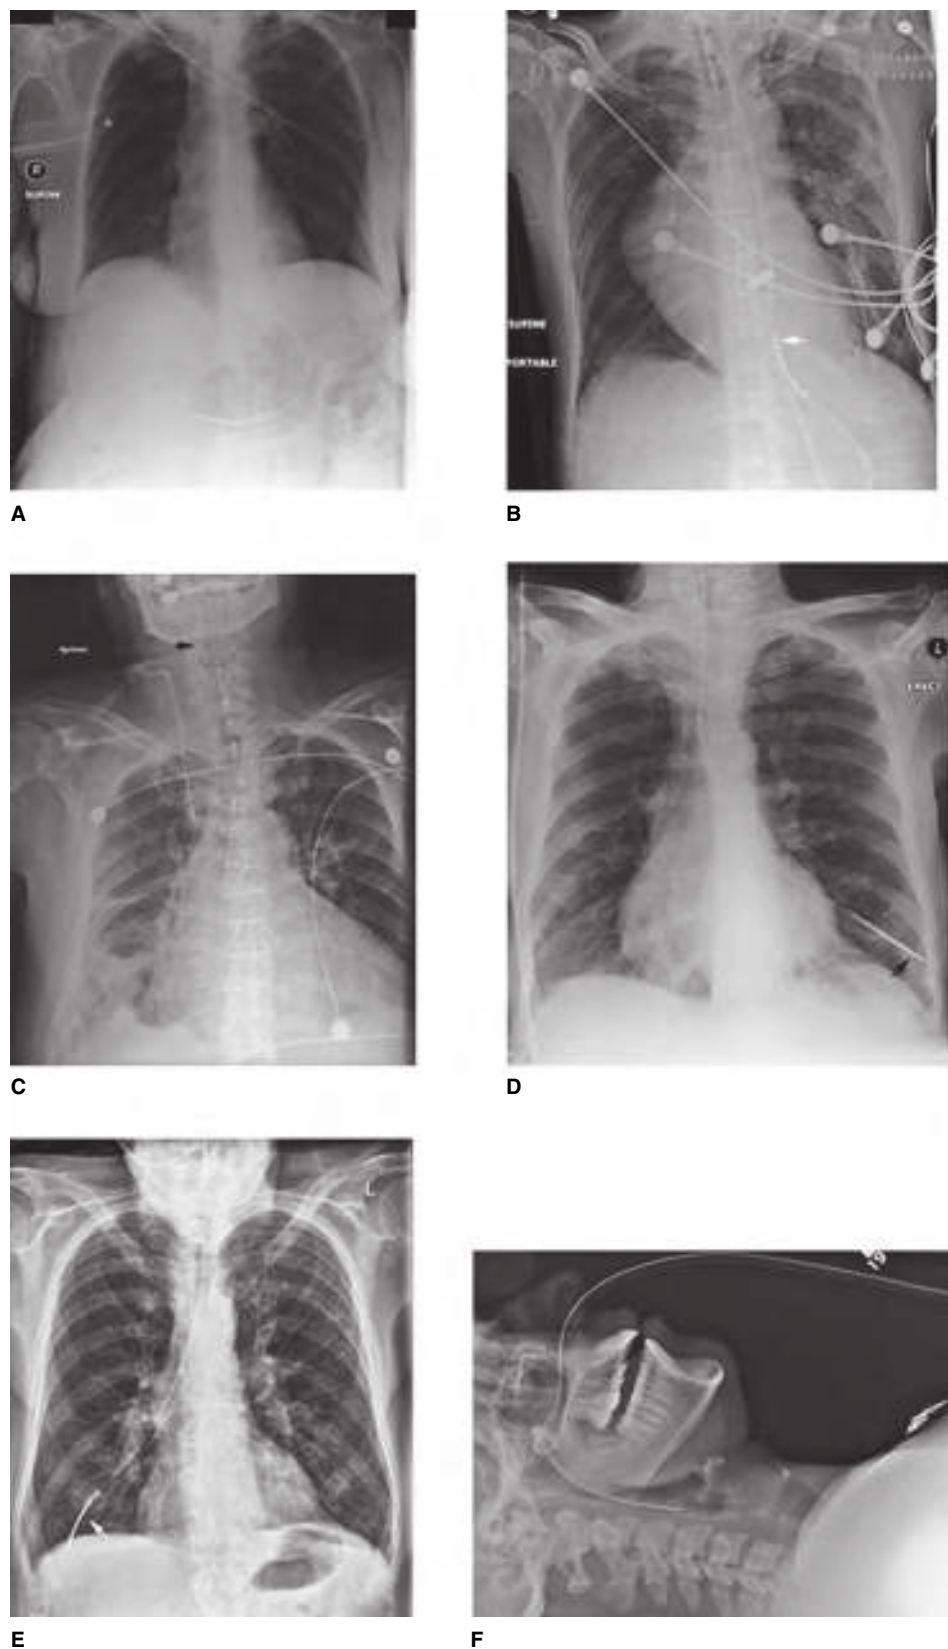

FIGURE 75-6. Radiographs of the inserted NG tube. **A.** The tip of the NG tube is in the stomach. **B.** The tip of the NG tube is in the esophagus after it curves in the stomach. **C.** The tip of the NG tube is coiled in the hypopharynx. **D.** The tip of the NG tube is in the left lower lobe of the lung. **E.** The tip of the NG tube is in the right lower lobe of the lung. **F.** The NG tube is knotted in the nasopharynx. (Photos used with permission from www.wikiradiography.net.)

NG tube. Testing the pH of the gastric contents can help predict the placement of the NG tube. The pH of the aspirated fluid will be ≥ 7 in 99% of patients if the NG tube is in the respiratory tree.⁴³ The pH of the aspirated fluid will be ≤ 5 in 70% of the patients if the NG

tube was correctly placed in the stomach. The use of H_2 blockers or antacids makes the assessment of gastric pH difficult.

Radiography is the most reliable and should be strongly considered when the NG tube is to be used for medication administration

FIGURE 75-7. Ultrasound images of the esophagus without (left) and with (right) the NG tube. CA, carotid artery; SCM, sternocleidomastoid muscle. (Used with permission from reference 50.)

or alimentation.⁴² Radiographic demonstration of the tube in the antral or fundal portion of the stomach is the preferred method of confirmation.^{41,44,45} Make sure the NG tube bisects the carina, avoids the bronchial contours, and crosses the midline diaphragm, and that the tip is visible under the left hemidiaphragm.^{41,45}

Multiple studies have shown the utility of ultrasonography to confirm NG tube placement in adults and children (**Figures 75-7 and 75-8**).⁴⁶⁻⁵² Use a high-frequency linear transducer. The endotracheal tube can be visualized as it passes through the esophagus below the level of the cricoid cartilage. Ultrasound can be used to verify the position of the NG tube after insertion. A chest radiograph should still be obtained if the ultrasound suggests the NG tube is not located in the stomach.⁵³

(Used with permission from reference 52.)

FIGURE 75-9. An NG tube is inserted into an oropharyngeal airway before being chilled in ice water. The chilled NG tube will retain its curve for 30 to 60 seconds.

AFTERCARE

Secure the NG tube so it does not move.⁵⁴ Apply benzoin to the patient's nose. Apply tape to the nose and around the NG tube to secure it in place (**Figure 75-10**). Attach the NG tube to wall suction as needed.

NASOGASTRIC TUBE REMOVAL

Explain to the patient the procedure and what they will experience as the NG tube is removed. It is recommended for Emergency Physician to wear gloves, a mask with an eye shield, and a gown to

FIGURE 75-10. Securing the NG tube. Apply tincture of benzoin to the bridge of the nose. A piece of tape is attached to the nose with the distal end split into two and intertwined around the NG tube.

prevent being contaminated during the removal. Place the patient in the seated position. Place towels or pads over the patient's neck and chest. Have an emesis basin, tissues, and Yankauer suction immediately available. Disconnect the NG tube from suction. Fold over the proximal end of the NG tube and hold it tightly. Ask the patient to slightly flex their neck, breath in, and hold it. Place a drape or towel around the NG tube as it is exiting the patient's nose. Firmly squeeze the drape around the NG tube. Briskly withdraw the NG tube through the drape. The drape will contain all the secretions and bodily fluids to prevent them from splashing on the patient or the Emergency Physician. Discard the NG tube and the drape.

COMPLICATIONS

There are many complications associated with a NG tube (**Table 75-1**).⁵⁵ The most common complication of NG intubation is discomfort in the nasopharynx and oropharynx. Placement in the nares can result in epistaxis if the nasal mucosa is abraded, irritated, or ulcerated. These complications can be reduced or avoided

TABLE 75-1 Some of the Complications Associated with the NG Tube

Breakage
Bronchial perforation
Bronchial placement
Discomfort
Double-backing of the tube
Empyema
Epistaxis
Erosion into adjacent structures
Esophageal perforation
Fistulas
Gastric perforation
Intracranial entrance
Kinks in the tube
Knotted tube
Lung perforation
Misplacement
Obstruction
Pneumothorax
Pulmonary hemorrhage
Rupture
Sinusitis

with generous lubrication of the NG tube, the instillation of topical anesthetics, and the instillation of vasoconstrictors prior to inserting the NG tube. Sinusitis may occur from the NG tube obstructing the sinus ostia. These complications are usually of no clinical significance. Difficulty in insertion or removal can result in coiling in the hypopharynx (**Figure 75-6C**), knotting around the endotracheal tube, or knotting of the distal end (**Figure 75-6F**).^{56,57}

A serious consequence of NG intubation is misplacement into the respiratory tree (**Figures 75-6D and 75-6E**).^{58,59} **This is estimated to occur in up to 15% of cases.**⁶⁰ The incidence increases in frequency with the patient who has a diminished gag reflex or a decreased level of consciousness. **The presence of a cuffed endotracheal tube does not preclude passage into the respiratory tree.** The NG tube will pass the cuff of the endotracheal tube without significant resistance. Advancing the NG tube into the airway can result in a bronchopulmonary fistula, an empyema, a hydropneumothorax, perforation of a bronchus or the lung, a pneumothorax, or a pulmonary hemorrhage.⁶⁰ **These complications are increased if medication or alimentation is infused into the respiratory tree.**

A serious complication of NG tube placement is esophageal perforation.⁶¹ This most often occurs in the posterior wall of the cervical portion of the esophagus and through the cricopharyngeus muscle. Risk factors for esophageal perforation include altered mental status, cardiomegaly, cervical osteophytes, esophageal abnormalities, multiple attempts, stiff NG tubes, and tracheal intubation.⁴² Other risk factors for esophageal perforation include esophageal cancer or the ingestion of alkaline substances. Perforation often results in mediastinitis with a subsequent mortality rate of up to 30%.⁴² Parenteral antibiotics, prompt recognition, and surgical repair can reduce the mortality rate to less than 10%. The use of softer and smaller NG tubes with generous lubrication can reduce the risk of esophageal perforation. The NG tube can rarely perforate the stomach in cases of connective tissue disease, gastric surgery, and peptic ulcer disease.⁶²

Use caution when inserting an NG tube in patients who have suffered trauma to the face, neck, and/or skull, or if they have medical conditions affecting these areas.^{42,63} Fractures of the base of the skull, cribriform plate, maxilla, nasal walls, orbital floors, and palate may allow a nasally inserted tube to exit the nasal cavity and cause further injury. The NG tube may exit traumatic or medical wounds and penetrate neighboring vascular structures.^{63,64}

SUMMARY

NG intubation is commonly performed in the Emergency Department. It is primarily used to evacuate air and stomach contents in the bowel-obstructed, intubated, or poisoned patient. Placement is generally considered easy, although it can be uncomfortable. Studies suggest that generous lubrication, topical anesthetics, and topical vasoconstrictors can diminish the discomfort and reduce the chance of misplacement.

Placement of the NG tube into the airway or coiled in the esophagus can result in serious complications. Auscultation of air has been classically used to determine correct placement. Radiographic confirmation of gastric placement is considered the gold standard. Carefully observe the patient for signs of esophageal perforation.

Activated Charcoal Administration

Jenny J. Lu

INTRODUCTION

The adsorptive capacity of charcoal has been documented since the time of Hippocrates and has been known for centuries. Two independent researchers were responsible for its wide acceptance in the early nineteenth century when each of them performed a demonstration of its effectiveness by ingesting lethal doses of strychnine and arsenic, respectively, followed by charcoal. Both of them survived. The twentieth century has seen charcoal come into wide medical use as further investigation showed its effectiveness at adsorbing a variety of compounds.¹ **Activated charcoal is currently the most commonly used mode of decontamination in the Emergency Department for poisoned patients.**²

ANATOMY AND PATHOPHYSIOLOGY

Charcoal is produced by the distillation of the pyrolysis products of vegetable matter or wood. It works by directly adsorbing toxicants via a variety of chemical binding properties and preventing substances in the gastrointestinal tract from being absorbed into the circulation. Enhancement of the adsorptive capability of charcoal is achieved by heating it to a temperature of 900°C and then subjecting it to a stream of oxidizing gas (e.g., carbon dioxide or steam). This process is termed “activation” and creates an internal pore structure that increases the surface area from 2 to 4 square meters per gram to greater than 2000 square meters per gram (**Figure 76-1**).² A typical dose of 50 gm of activated charcoal has the surface area of 10 football fields. **Activated charcoal is not absorbed from the intestinal lumen nor is it modified by the numerous enzymes that aid in the digestion of food.** It passes through the intestinal tract unchanged and is expelled as a sticky black substance.

Some activated charcoal preparations contain sorbitol. Sorbitol is used as a flavoring agent to make food, drinks, and medications more palatable. It is also used as a hyperosmotic laxative agent. It is poorly absorbed from the gastrointestinal tract and is converted into fructose by the liver. **Its limited absorption results in an increased volume of water being secreted into the intestine causing an increased intraluminal pressure that stimulates catharsis.**

Activated charcoal is usually used for decontamination, in single or multiple doses. **Multiple doses of activated charcoal are considered in exposures to drugs with sustained- or delayed-release preparations or in situations where there is evidence of ongoing absorption.** Multiple-dose activated charcoal can help enhance the elimination of certain compounds that exhibit enteroenteric or enterohepatic recirculation. A diffusion gradient is created in

FIGURE 76-1. Activated charcoal.

the intestine when multiple-dose activated charcoal is given for enhanced elimination due to the enormous adsorptive ability of charcoal to bind free toxicant. The intestinal mucosa functions as a semipermeable membrane, allowing absorbed drug or toxin to diffuse from the capillaries back into the lumen of the intestine. Activated charcoal can then adsorb and “trap” the toxin within the intestinal lumen for its subsequent excretion in the stool.^{3,4} This mechanism essentially dialyzes the blood in the capillaries of the intestinal circulation, hence the term “gastrointestinal dialysis.”

Drugs and drug metabolites secreted into the bile may be absorbed and trapped by activated charcoal within the intestinal lumen. Activated charcoal may shorten the half-life by adsorbing these substances, although evidence for clinical benefit remains limited. Substances that may benefit from multiple-dose activated charcoal for enhanced elimination include phenobarbital, theophylline, dapsone, diazepam, amitriptyline, carbamazepine, phenytoin, quinine, salicylates, piroxicam, digoxin, doxepin, quinine, tricyclic antidepressants, and meprobamate.³⁻⁵

Activated charcoal has an excellent safety profile overall. It can be used in pregnancy, in lactation, and in the pediatric population. Its use is widely accepted by Emergency Physicians without good randomized controlled clinical studies demonstrating a mortality outcome benefit.⁴ Studies supporting activated charcoal’s efficacy include in vitro, animal, and volunteer studies. Activated charcoal has been found to be just as efficacious when compared with emetics or gastric lavage as a single modality for decontamination. A large randomized controlled trial examined gastric emptying procedures and compared ipecac-induced emesis, gastric lavage, and activated charcoal in patients with drug overdoses.⁶ No significant differences were found in clinical severity, length of hospital stay, morbidity, or mortality among the treatment groups. These findings are similar to those found in other studies.^{7,8}

Ipecac-induced emesis, activated charcoal, and gastric lavage were compared in volunteers 1 hour after the ingestion of ampicillin.⁹ Activated charcoal was found to be superior in decreasing the absorption of blood ampicillin levels by 57%. Gastric lavage decreased absorption by 32%, and emesis decreased it by 38%. The authors concluded that activated charcoal without a gastric emptying procedure may be the preferred method of gastrointestinal decontamination. Limitations of the study included using subtoxic doses of ampicillin on volunteers and the small sample size.

INDICATIONS

Activated charcoal is currently considered the modality of choice for gastrointestinal decontamination.^{10,11} It is generally indicated for ingestions considered to be serious or life-threatening and that are adsorbable to charcoal.

The optimal timing for administration of activated charcoal remains debatable and depends on the exposure and the individual case. It is generally agreed that the sooner after an ingestion the better.¹² There may be clinical scenarios in which delayed administration is appropriate, including exposures where there is evidence of delayed or ongoing absorption (e.g., salicylates). The American Academy of Clinical Toxicology has noted that there is insufficient evidence to support or exclude the use of activated charcoal more than 1 hour after a toxic ingestion.¹²⁻¹⁴ One observational study found lower rates of liver injury in acetaminophen-poisoned patients presenting more than 4 hours after ingestion who were administered both activated charcoal and *N*-acetylcysteine.¹⁵ The pros and cons of activated charcoal should be weighed on a case-by-case basis, regardless of time frame.¹⁶⁻²⁰

CONTRAINDICATIONS

One absolute contraindication to the use of activated charcoal is in the patient with an unprotected airway. Patients with depressed levels of consciousness and those at risk for seizures from their toxic ingestions are at higher risk of aspiration. It is not recommended that patients be endotracheally intubated solely for the purpose of administering activated charcoal. Patients with absent bowel sounds, evidence of gastrointestinal obstruction, or recent gastrointestinal surgery should not be given activated charcoal due to the risk of bezoar formation or perforation and leakage of charcoal into the abdominal cavity.

Activated charcoal is not effective against xenobiotics such as acids and alkalis, alcohols, fluoride, heavy metals, inorganic salts, iron, lithium, or potassium. Its use is limited in liquid ingestions where absorption is rapid. It is unlikely to be helpful in hydrocarbon and pesticide ingestions. Administration of activated charcoal can render endoscopic visualization technically difficult. **Charcoal combined with cathartics is contraindicated in young children due to the risk of severe electrolyte imbalances and should be used with caution in renally impaired patients.**^{21,22}

EQUIPMENT

Several charcoal preparations are available (Figures 76-2 and 76-3).²³ These include capsules, tablets, powder, oral suspensions, and suspensions containing sorbitol. Powder, premixed oral suspensions, and suspensions with sorbitol are the only preparations indicated for use in an acute poisoning. Powder is available in doses from 15 to 500 gm that must be mixed with water to make a slurry. The premixed suspension is available in strengths of 12.5 gm/60 mL to 50 gm/240 mL. Activated charcoal suspensions with sorbitol are available containing 25 to 50 gm of activated charcoal and 25 to 96 gm of sorbitol in a volume of 120 to 150 mL. Some Emergency Departments and hospitals mix sorbitol with the activated charcoal when it is required. The recommended dose is 1 to 2 gm/kg in adults, 1 to 2 mL of the 70% solution of sorbitol in adults, and 4.3 mg/kg of the 35% solution of sorbitol in children.²²

PATIENT PREPARATION

The airway should be evaluated in any patient who has ingested a central nervous system depressant, tricyclic antidepressants, a sympathomimetic or other agent that may result in seizures, or any

substances that can cause an altered mental status. Airway protection should be provided if clinically indicated prior to the administration of activated charcoal in patients who are comatose, drowsy, obtunded, unconscious, or have an absent or impaired gag reflex.

TECHNIQUE

Activated charcoal should ideally be administered as early as possible after an ingestion as its efficacy is reduced with the passage of time. Thoroughly mix the activated charcoal slurry prior to opening the container. The activated charcoal may settle at the bottom of the container. **An aqueous slurry should be used rather than tablets or powder.** A single dose is typically administered. Multiple doses may be considered if the toxicant is expected to be absorbed slowly (e.g., massive ingestions or sustained-release preparations) or if enhanced elimination of already absorbed substances (i.e., through enteroenteric or enterohepatic recirculation) is the objective. The ideal dose for the single or initial dose is 5 to 10 times the amount (in grams) of toxicant ingested. Standard practice is to administer 1 gm/kg (i.e., 50 to 100 gm to an adult or 10 to 25 gm to a child < 5 years).²³ Repeated doses may range from 15 to 30 gm every 2 to 4 hours. The optimal dosing is not known.²³ An alert patient typically tolerates drinking the slurry well. Nausea and vomiting can be alleviated with the administration of an antiemetic medication.

Sorbitol may be premixed with the activated charcoal. The sorbitol will decrease gastrointestinal transit time and may prevent bezoar formation. **Sorbitol-containing charcoal should be given only to adults and only with the first dose. Attention should be paid to verify whether or not the charcoal preparation contains sorbitol, especially where multiple doses are given.** Monitor hydration and electrolyte levels if multiple doses of sorbitol-containing activated charcoal are given.

A nasogastric tube (Chapter 75) can be placed to facilitate administration of the activated charcoal. **Correct placement of the nasogastric tube in the gastrointestinal tract is essential prior to activated charcoal administration.** Confirmation of gastric placement can be achieved with the auscultation of insufflated air through the nasogastric tube into the stomach over the epigastrium, the aspiration of stomach contents through the nasogastric tube, or radiographically demonstrating the nasogastric tube below the level of the diaphragm. Minimize gastric pressures caused by the overly aggressive administration, which can increase the risk of aspiration.²⁴

COMPLICATIONS

The most feared complication of activated charcoal use is pulmonary aspiration. Activated charcoal can cause severe pneumonitis that can lead to respiratory failure, prolonged ventilatory support, and death. The activated charcoal can cause an empyema and bronchiolitis obliterans if aspirated. **Avoiding aspiration is a priority when giving activated charcoal.** Awake patients must have an intact gag reflex in order to protect against aspiration. Errant placement of a nasogastric tube into the trachea or bronchi and past the inflated cuff of a properly placed endotracheal tube can result in aspiration.²¹ **The proper placement of a nasogastric tube must be confirmed prior to instilling activated charcoal.** Reports of life-threatening pulmonary complications as a result of aspiration have also been reported with the removal of the nasogastric tube subsequent to activated charcoal administration.²⁵ Aspiration of activated charcoal can occur in the intubated patient with an inflated endotracheal cuff and properly placed nasogastric tube.²⁶

Activated charcoal containing sorbitol or given with magnesium decreases the risk of intestinal obstruction and constipation.

C

D

E

FIGURE 76-2. Several of the preparations of activated charcoal used in the Emergency Department.

Cathartics may induce other problems. Electrolyte disturbances can result despite the benefits of decreasing transit time through the gut and the concomitant decrease in toxicant absorption. Cathartic-induced hypernatremia, typically a complication seen in the very young, can lead to serious central nervous system damage, brain

swelling, long-term morbidity, and death. Sorbitol dosing in children is not clearly established. The typical premixed preparations are not appropriate in the pediatric population. Hypermagnesemia is seen in the adult population when a magnesium-containing cathartic is given to a patient with gastrointestinal abnormalities or

FIGURE 76-3. Capsules of activated charcoal.

renal compromise. Dehydration is a problem encountered in the elderly and very young. Osmotic volume loss from the gastrointestinal tract can cause these fragile populations to decompensate.²¹

Intestinal obstruction is a rare complication but carries significant morbidity. Case reports of obstruction and perforation requiring a laparotomy have been reported. Charcoal bezoars are the usual culprits. Bezoars can form when intestinal motility is compromised, allowing continued absorption of water from the intestinal contents. Bonds form between charcoal particles once sufficient water has been absorbed and the mass continues to harden. Ingestions of anticholinergic substances, antiperistaltic co-ingestions, or medications administered during the hospital course have also been implicated. Use caution when giving these patients narcotic or anticholinergic medications. Patients receiving multiple-dose activated charcoal therapy or activated charcoal without cathartics are at greater risk. Constipation is a milder form of this complication and is uncommon and rarely of clinical significance.²¹

SUMMARY

Activated charcoal is currently the most commonly used modality of gastrointestinal decontamination in the acutely poisoned patient. This is despite limited evidence demonstrating improved clinical outcomes or decreased mortality rates. Administration of activated charcoal is relatively straightforward and well tolerated. The usual dose of activated charcoal is 50 to 100 gm in an adult and 1 gm/kg in a child. Preparations containing a cathartic (e.g., sorbitol) can be used with the first dose in the adult unless contraindicated. Cathartics and charcoal preparations containing sorbitol should not be used in children or those with renal impairment due to the risk of electrolyte disturbances. The most significant complications occur as a result of aspiration and can be minimized by paying close attention to the patients at risk (i.e., a decreased level of consciousness or a weakened gag reflex) and by checking placement of the nasogastric tube prior to administration of activated charcoal. The risks and benefits of multiple-dose activated charcoal for decontamination or for enhanced elimination must be carefully weighed. Activated charcoal may be judiciously administered

in appropriately selected poisoned patients as long as there are no contraindications. The decision to use activated charcoal should be determined on a case-by-case basis by the treating Emergency Physician, with possible consultation from a poison control center or a Toxicologist.

Gastric Lavage

Jenny J. Lu and Rosaura Fernandez

INTRODUCTION

Gastric lavage is a method of gastrointestinal decontamination, performed in the setting of an acute poisoning by ingestion, to decrease the absorption of substances in the stomach. This technique was first described in 1812 and has been used for nearly 200 years.¹ It was repopularized in the 1950s and 1960s and thrived during the heyday of the “tricyclic era” of the 1970s and 1980s. **The use of gastric lavage in the Emergency Department has decreased greatly in modern toxicology. Various sources continue to reiterate the potentially serious complications with this procedure. Trends toward evidence-based medicine and the growing body of experimental and clinical data point to the limited efficacy of gastric lavage.** Gastric lavage was performed in approximately 10.3% of all ED-treated poisoning cases between 1998 and 2003, a decrease from 18.7% during the period of 1993 through 1997.² The increasing use of other modalities for gut decontamination (e.g., activated charcoal) has further limited the role of gastric lavage.^{1,3} The American Academy of Clinical Toxicology (AACT) states that “gastric lavage should not be performed routinely, if at all, for the treatment of poisoned patients.”⁴

ANATOMY AND PATHOPHYSIOLOGY

The administration of activated charcoal is the current decontamination measure of choice. There remain very few indications for performing gastric lavage. These indications include a highly toxic or potentially lethal ingestion presenting acutely where no antidote exists, no antidote is available, or other usual therapies are ineffective. Gastric lavage has never been demonstrated to decrease mortality or improve the final outcome of the patient. The decision should be made with consideration to the specifics of the individual case.

The optimal timing to perform gastric lavage is controversial. **The efficacy of gastric lavage diminishes rapidly over time.** Any benefit of gastric lavage would likely be gained if performed promptly and within 1 hour of an oral ingestion.³ Authors agree that sooner is better. The range of recovered ingested is highly variable at each time point following an ingestion in volunteer and overdose studies. The trend for mean removal of ingested is 90% recovery at 5 minutes postingestion, 45% recovery at 10 minutes, 30% recovery at 19 minutes, and as little as 8% recovery at 60 minutes.³ Delayed gastric lavage should be considered only in a severe poisoning where delayed gastric emptying is suspected. Some toxicants or co-ingestants (e.g., anticholinergics or opioids) may cause delayed gastric emptying, whereas others may form masses or concretions in the stomach. Removal of a percentage of the ingested dose may theoretically lessen the severity of the poisoning in some cases, but these benefits remain unproven.

Nasogastric placement of a gastric lavage tube is not advised. The orogastric route should be used to avoid traumatic injury to the nasal mucosa, nasal turbinates, and nasal septum. **Nasogastric tubes should be limited to liquid overdoses.** Lavage fluid that does not return through the nasogastric tube will pass through the pyloric sphincter and could allow increased absorption of the toxicant.⁵ Sustained-release tablets or capsules are particularly large in size and unlikely to be removed through a nasogastric tube or through the fenestrae of a 40 French orogastric lavage tube (Figure 77-1).

FIGURE 77-1. Orogastric lavage tubes demonstrating sideport size. A 36 French tube with a Stresstab 600 multivitamin in the sideport (top). A 40 French tube with a 450 mg sustained-release theophylline tablet in the side port (middle). A generic 250 mg ampicillin tablet (bottom).

Placement of gastric lavage tubes in the pediatric population is precarious (Figure 77-2).⁶ A formula for the depth of insertion has been prospectively evaluated to ensure adequate placement in this population and is depicted graphically in Figure 77-3.^{6,7} The size of the oropharyngeal aperture and esophagus are proportional to the

FIGURE 77-2. Malposition of an orogastric tube placed for gastric lavage in a pediatric patient. (Courtesy of Ann E. Klasner, MD, MPH.)

FIGURE 77-3. Estimated lavage tube insertion depth in children based on their height. The lengths for both nasogastric (NG) and orogastric (OG) tubes are represented on the graph. (Used with permission from reference 6.)

size of the individual. **Appropriate tube diameter is essential to minimizing complications.**

INDICATIONS

Gastric lavage may be considered for immediate stomach emptying within 1 hour for an ingestion determined to be potentially serious or life-threatening or where antidotal or other supportive modalities are unavailable or inadequate (Table 77-1).^{4,8} Preference should first be given to other less invasive modalities of gastrointestinal decontamination (e.g., activated charcoal). Consideration should be given to the specific characteristics of the toxicant, the ingested dose, and the risks versus benefits of performing the procedure. It may be considered beyond 1 hour in patients with known or suspected delayed gastric motility (e.g., in the setting of anticholinergic or opioid ingestion) or where the evidence of a durable mass (e.g., concretion) of pill fragments is a concern.

TABLE 77-1 Indications for Performing a Gastric Lavage

Acute presentation (within 1 hour) and:

1. Evident or high risk of morbidity or mortality

Beta-blockers	Heterocyclic antidepressants
Calcium channel blockers	Iron
Chloroquine	Paraquat
Colchicine	Salicylates
Cyanide	Selenious acid
Heavy metals	

2. Poor absorption by activated charcoal

Heavy metals
Iron
Lithium
Toxic alcohols

3. Evidence of formed concretion

Enteric-coated preparations
Iron
Phenothiazines
Salicylates

4. Ineffective or no antidotal therapy available

Cellular poisons (e.g., colchicine)
Paraquat
Selenious acid

CONTRAINDICATIONS

The contraindications to performing a gastric lavage are summarized in Table 77-2. **An absolute contraindication to gastric lavage is in a patient with a depressed level of consciousness who cannot protect their airway.** Gastric lavage should not be performed in combative patients, patients at high risk of seizures, and in those who may be expected to deteriorate rapidly. **Intubating a patient solely for the purpose of gastric lavage is not recommended.** Gastric lavage is contraindicated in caustic ingestions. Local mucosal damage amplifies the risk for traumatic perforation. Gastric lavage should not be performed to retrieve large pills, large foreign bodies, or sharp foreign bodies. It is relatively contraindicated in hydrocarbon ingestions, especially where there is high pulmonary aspiration potential. Significantly abnormal upper airway or upper gastrointestinal anatomy (e.g., anomalies, strictures, or a fresh interposition graft) may restrict the use of gastric lavage.

Gastric lavage is contraindicated in the vomiting patient due to the risk of aspiration and perforation. Vomiting is common after many overdoses and may itself serve as a “natural” decontamination measure. Multiple episodes of emesis may clear the majority of a toxicant from the stomach and obviate the need for gastric lavage. Vomiting in the setting of caustic ingestions can cause further harm by reexposing the gastrointestinal mucosa to the caustic substance. Attempts at gastric intubation in the setting of an actively vomiting patient are likely to be met with minimal success and may cause injury.⁹

Gastric lavage is unlikely to change the outcome of a nontoxic or minimally toxic ingestion. The risk-benefit ratio is unacceptably high in such cases. The determination of whether or not to perform

TABLE 77-2 Contraindications to Performing a Gastric Lavage

Abnormal or absent pharyngeal or upper gastrointestinal anatomy
Active or substantial antecedent vomiting
Caustic ingestion
Coagulopathy
Combative or uncooperative patient
Decreased level of consciousness
Diminished or absent airway reflexes
Large pills
Large or sharp foreign body
Nontoxic or minimally toxic ingestion
Significant aspiration risk (e.g., hydrocarbon ingestion)
Seizures/high risk of seizures

a gastric lavage must be individualized. Consult a Medical Toxicologist or poison control center in questionable cases.

EQUIPMENT

- Pulse oximeter
- Cardiac monitor
- Noninvasive blood pressure monitor
- Protective clothing
- Bite block
- Oral airway
- Endotracheal tube and intubation equipment (Chapter 18)
- Endotracheal tube stabilizer
- Emesis basin
- Suction source, tubing, and Yankauer suction catheter
- Orogastic tube 36 to 50 French for adults or 24 to 34 French for children
- Large bulb suction device or 50 mL Toomey syringe
- Warm water or normal saline for adults
- Warm normal saline for children
- Water-soluble lubricant
- Activated charcoal (optional)
- Resuscitative equipment

All required instrumentation should be gathered at the bedside prior to initiating the procedure. A variety of orogastric lavage tubes are available. Most have a distal port and at least one sideport. A semirigid tube is preferable to soft rubber or polyvinyl chloride collapsible tubes. Several additional ports should be cut in the sides of the tube near the tip to maximize the return of pill fragments if the tube has only a single sideport. Examples of rigid tubing are shown in **Figures 77-1 and 77-4**. A larger tube diameter provides less flexibility and ensures the tube is less likely to kink, collapse, or curl back on itself. Larger-diameter tubes are more likely to facilitate retrieval of larger pill fragments. A 30 to 50 French lavage tube is preferred in an adult. A 30 to 34 French tube is adequate for an adolescent. Small children can generally accommodate 24 French tubes. Gastric lavage is generally contraindicated in neonates and infants.

There are numerous types of gastric lavage systems. Open systems are less expensive, messy, and time-consuming to use. A passive open system uses gravity to instill and drain the lavage fluid. An active open system uses a large syringe to inject and aspirate lavage fluid through the orogastric tube. The syringe must be removed from the orogastric tube to be filled with fresh lavage fluid, and used lavage fluid must be discarded after each lavage cycle. Closed systems are commercially available, single-patient use, self-contained, easy to use, and do not cause a mess (**Figure 77-4**). The Emergency Physician should be familiar with the type of equipment available at their institution.

Gastric lavage solution typically consists of tap water or normal saline. **Do not use tap water in small children as this can result in electrolyte abnormalities.** Specialized lavage solutions may be indicated if the ingested substance is fluoride, formaldehyde, iodine, iron, or oxalic acid. Fluoride ingestions may be lavaged with 15 to 30 gm/L of calcium gluconate to produce an insoluble calcium fluoride. Formaldehyde ingestions may be lavaged with 10 mg/L of ammonium acetate to produce the nontoxic substance methenamine. Iodine ingestions may be lavaged with 75 gm of cornstarch in 1 L of water. Iron ingestions may be lavaged with 2% sodium bicarbonate (e.g., 50 mEq in 150 mL of normal saline) to produce the insoluble ferrous carbonate. Oxalic acid ingestions may be lavaged with 15 to

FIGURE 77-4. Example of a closed lavage pump system. (Courtesy of Kimberly-Clark Corporation.)

30 gm/L of calcium gluconate to form the insoluble calcium oxalate. **These specialized lavage solutions should be used only in consultation with a Medical Toxicologist or poison control center.**

PATIENT PREPARATION

Explain the indications, details of the procedure, risks and benefits, and alternatives with the patient and/or their representative. Informed consent should be obtained when possible.

Place the patient in the left lateral decubitus position and in 15° to 20° of Trendelenburg. This position is intended to maximize gastric emptying. The supine and lateral decubitus positions are associated with a higher risk of pulmonary aspiration in comatose and mechanically ventilated patients.¹⁰⁻¹³ Most gastric lavages can be performed safely and effectively with the conscious patient placed in the semi-upright position. The use of a topical anesthetic spray into the oropharynx may decrease the patient's gag reflex and allow easier passage of the orogastric tube. This can also increase the risk of aspiration. It is recommended that a cardiac monitor, noninvasive blood pressure cuff, and pulse oximeter be placed on the patient prior to performing the lavage.

TECHNIQUE

Measure the length of the orogastric lavage tube to be inserted (**Figure 77-5**). The length should be marked with a permanent marker or a piece of surgical tape. Liberally lubricate the tip of the lavage tube. Place a bite block into the patient's mouth if they are conscious. A bite block or oral airway may preclude biting of the tube by an uncooperative or stuporous patient.¹⁴

Gently insert the lavage tube into the patient's mouth and direct it into the hypopharynx. Flexion of the patient's neck may facilitate

FIGURE 77-5. Determining the proper length of orogastric tube to insert. **A.** The length is determined by the distance from the xiphoid process to the tip of the nose to the earlobe. **B.** The length is determined by the distance from the tip of the nose or lip, around the left ear, and to just below the left costal margin. A piece of tape is used to mark the distance on the orogastric tube.

passage of the tube into the esophagus and avoid endotracheal insertion. Conscious and cooperative patients may be asked to swallow water through a straw or their saliva to facilitate passage of the tube. Stridor, cough, or cyanosis indicates that the lavage tube is in the airway and should prompt removal of the tube. Significant resistance is occasionally met in the hypopharynx. Apply gentle pressure to the tube while instructing the patient to swallow allows passage through the upper esophageal sphincter. **The tube should not be forced, as misplacement may damage the larynx or perforate the pyriform sinus.** Slowly advance the tube to the premeasured depth.

Confirmation of intragastric tube placement must precede instillation of any fluid through the tube. Proper placement should be confirmed by aspiration of gastric contents, auscultation of insufflated air over the epigastrium, and/or radiography. Gastric irrigation should be preceded by aspiration of available gastric contents. The initial aspirate may be sent for toxicologic assay.

Perform the gastric lavage. Instill normal saline or tap water through the lavage tube. The lavage fluid should ideally be warmed to body temperature. This is often not practical, and room temperature lavage fluid is satisfactory. Instill aliquots of 10 to 15 mL/kg to a maximum of 300 mL of the irrigant solution. Instillation of larger volumes may result in vomiting, pulmonary aspiration, and the passage of gastric contents past the pyloric sphincter where subsequent

absorption may occur.² Lavage aliquots may be instilled by placing a funnel in the free end of the lavage tube and allowing gravity instillation, or they may be infused with a Toomey syringe. Remove the lavage fluid after a brief (i.e., 1 to 2 minutes) equilibration period by either gravity drainage into an emesis basin or aspiration (e.g., a syringe or suction bulb). Repeat the lavage process until 2 to 3 L of irrigant has been used in the adult or the lavage fluid is free of particulate matter and pill fragments. Alternatively, closed systems are available for both instilling and suctioning lavage fluids through a common tube (Figure 77-4).

Activated charcoal (Chapter 76) may be administered, if desired, through the lavage tube before it is removed. A dose of 1 gm/kg of body weight is typically given initially, either in a premixed slurry or diluted in normal saline or tap water (e.g., 30 gm charcoal per 240 mL of diluent).

Remove the lavage tube. It is recommended for the Emergency Physician to wear gloves, a mask with an eye shield, and a gown to prevent being contaminated during the removal. Place towels or pads over the patient's neck and chest. Have an emesis basin, tissues, and Yankauer suction immediately available. Disconnect the lavage tube from its proximal attachment. Fold over the proximal end of the lavage tube and hold it tightly. Ask the patient to slightly flex their neck, breath in, and hold it. Place a drape or towel around the lavage tube as it is exiting the patient's mouth. Firmly squeeze the drape around the lavage tube. Briskly withdraw the lavage tube through the drape. The drape will contain all the secretions and bodily fluids and prevent them from splashing on the patient or the Emergency Physician. Discard the lavage tube and the drape.

Further gastric access, when needed, should be provided by the subsequent placement of a smaller-bore nasogastric tube.

ALTERNATIVE TECHNIQUES

An alternative sequence could be considered because of concern over toxicants passing or being pushed through the pyloric valve during the gastric lavage procedure. Administer activated charcoal after the initial aspiration of gastric contents through the lavage tube. Perform the gastric lavage anticipating that a significant amount of activated charcoal will be removed along with the ingested. Infuse a second dose of activated charcoal through the lavage tube before it is removed. The rationale here is an attempt to make charcoal available to adsorb toxicant from any gastric contents pushed into the small bowel during the lavage procedure.¹ It is reasonable to consider even though no data support this technique.

ASSESSMENT

Continuously monitor the patient and reassess them throughout the procedure. Strict adherence to the procedures noted will help minimize the risk of complications. Prompt removal of the lavage tube at the end of the procedure will help decrease the risk of delayed complications.

AFTERCARE

Most patients requiring gastric lavage for an overdose or poisoning usually require inpatient monitoring for their poisoning. A situation wherein a patient requires gastric lavage and is then sent home immediately is unlikely. An observation period of 6 to 8 hours for the immediate complications of gastric lavage and the effects of the ingested substance is appropriate.

COMPLICATIONS

The complications associated with gastric lavage can be minimized by careful patient selection and technique (Table 77-3).⁹ Placement of the lavage tube can result in mucosal injury, bleeding, esophageal

TABLE 77-3 Complications Associated with Gastric Lavage

Cardiac dysrhythmias
Electrolyte abnormalities
Empyema
Esophageal tear or perforation
Gastric perforation
Hypothermia
Laryngospasm
Nasal, oral, or pharyngeal injury
Pneumothorax
Pulmonary aspiration
Pyriiform sinus perforation
Tracheal placement
Tube impaction

perforation, gastric perforation, or endotracheal placement. Monitor the patient for cardiac arrhythmias, hypoxemia, and tachycardia.^{1,8} No more than 10 mL/kg or 300 mL aliquots of lavage fluid should be used to prevent vomiting, aspiration, or pushing of gastric contents into the small bowel. The impaction of a lavage tube may prevent its removal.^{1,9,15} **Do not use force to remove the lavage tube, as this may injure or rupture the stomach or esophagus.** Evaluate the tube using fluoroscopy or plain radiographs. A lavage tube that is kinked or knotted will require endoscopically aided or surgical removal.

Gastric lavage with large volumes of cold fluid can result in hypothermia. Warmed lavage fluid should be used if available, although this is somewhat controversial. Warm lavage fluid may dissolve more of the toxicant and allow rapid access of gastric contents past the pylorus to be absorbed into the systemic circulation. Electrolyte abnormalities may result, especially in children, if the lavage fluid is hypotonic (i.e., tap water). **The use of normal saline for gastric lavage is recommended.**

It is usually unknown if pills and/or pill fragments remain within the patient's stomach when they present to the Emergency Department. The routine use of CT scans to identify pills and/or pill fragments in the stomach cannot be recommended. Two case reports used CT scans to determine that pills and/or pill fragments remained in the stomach, and subsequently, gastric lavage was performed.^{16,17} There is no evidence that the expense and radiation exposure prevents any morbidity or mortality or provide any benefit to the patient.

SUMMARY

Gastric lavage is an invasive decontamination procedure to empty the stomach following a toxic ingestion. Its use has significantly decreased. There are rare indications in which gastric lavage could be considered. Maximal efficacy of the procedure would be obtained if performed within 1 hour of an acute ingestion. Gastric lavage is not indicated in the setting of a nontoxic ingestion, minimally toxic ingestion, or where antidotes exist and are readily available. Complications can be minimized if the procedure is performed cautiously. Consultation with a Medical Toxicologist or poison control center is prudent and can provide valuable information regarding the indications, contraindications, complications, and techniques associated with gastric lavage.

Whole Bowel Irrigation

Henry D. Swoboda and Steven E. Akl

INTRODUCTION

Whole bowel irrigation is the infusion of polyethylene glycol electrolyte lavage solution into the stomach at flow rates higher than are otherwise commonly used. This technique can be used to decontaminate the gastrointestinal tract after an acute toxic ingestion or overdose. **The goal is to give a large volume of a balanced electrolyte solution rapidly to flush the bowel without creating electrolyte disturbances while removing the ingested.** Most of the literature supporting its use is in the form of case reports or case series, with cohort studies indicating benefit that is of unclear clinical significance and does not support broad use of the therapy.¹ Demonstrated benefits are small.² The indications for whole bowel irrigation are mostly theoretical and will be refined as more extensive data becomes available.³ The role of whole bowel irrigation remains limited.

ANATOMY AND PATHOPHYSIOLOGY

Current methods of gastrointestinal decontamination (i.e., activated charcoal, emesis, and gastric lavage) focus primarily on decontaminating the stomach. Absorption of most toxicants occurs principally

TABLE 78-1 Conditions in Which Whole Bowel Irrigation Can Be Considered

1. Acute, life-threatening, or serious ingestion and hemodynamically stable
2. Any of the following:
 - Concretions
 - Delayed, enteric-coated, or sustained-release preparation
 - Heavy metals
 - Ingested packets of illicit drug
 - Iron
 - Lithium
 - Massive ingestions
 - Toxin or toxicant poorly adsorbed by activated charcoal

in the proximal small bowel. Sustained-release or delayed-release preparations continue to liberate the drug during intestinal transit that is then available for absorption throughout the bowel. Infusion of polyethylene glycol electrolyte lavage solution decreases the enteric transit time, attenuating the contact time of a toxicant with the gastrointestinal mucosa.⁴ This reduces absorption of the drug or toxin throughout the gastrointestinal tract. The high molecular weight PEG 3350 polyethylene glycol electrolyte lavage solution (PEG-ELS) is specifically designed to prevent electrolyte and fluid shifts.

INDICATIONS

Whole bowel irrigation may be indicated for acute ingestions where severe or potentially fatal toxicity is anticipated (Table 78-1). Use other decontamination methods (e.g., activated charcoal) if they are known to be effective rather than whole bowel irrigation. PEG-ELS has been shown to decrease the effectiveness of activated charcoal in some poisonings. An initial dose of activated charcoal may increase the effectiveness of whole bowel irrigation.^{5,6} Whole bowel irrigation may be indicated in situations where activated charcoal is known to be ineffective. Whole bowel irrigation has been safely used to decrease bioavailability of ingested iron, lithium, and heavy metals, and it may decrease the poisoning severity associated with lithium overdose.⁷⁻¹² Whole bowel irrigation has been proposed to be effective in flushing the gastrointestinal tract free of toxicant before absorption of sustained-release preparations.¹³ Whole bowel irrigation may speed gastrointestinal transit of ingested packets or vials of illicit drugs ingested by “body packers” who purposely ingest carefully prepared drugs as a means of internal concealment for transportation.¹⁴ The role of whole bowel irrigation in “body stuffers” who hastily ingest drugs to avoid legal prosecution has been questioned.¹⁵ Additional settings may be envisioned where whole bowel irrigation might be useful. There are no data to support broader indications.

CONTRAINDICATIONS

There are few contraindications to performing whole bowel irrigation (Table 78-2). **Do not use it in the patient with a potentially compromised or unprotected airway.** Whole bowel irrigation

TABLE 78-2 Contraindications to Performing Whole Bowel Irrigation

- Bowel obstruction or perforation
- Gastrointestinal bleed
- Gastrointestinal tract is not intact
- Hypotension or hemodynamic instability
- Ileus
- Indications to go to the Operating Room
- Intractable vomiting
- Nontoxic ingestion
- Potentially compromised or unprotected airway
- Significant gastrointestinal bleeding
- Signs of leakage of cocaine packets

could result in pulmonary aspiration.^{16,17} Significant vomiting will hinder the ability to perform whole bowel irrigation. Do not perform whole bowel irrigation in the hypotensive or hemodynamically unstable patient.¹⁶ Other contraindications include abnormal upper airway or upper gastrointestinal anatomy (e.g., anomalies, fresh interposition graft, or strictures). Ingestion of toxic substances that markedly slow gastrointestinal motility (e.g., anticholinergics or opioids) may cause an ileus, diminishing the ability to perform whole bowel irrigation effectively. The administration of polyethylene glycol in a patient with a bowel obstruction will result in vomiting with the potential for aspiration. Do not use polyethylene glycol solution with an actual or suspected perforated bowel. The risk of whole bowel irrigation is quite small, but the procedure is not without effort, expense, and risk of complications.¹⁸ The risk-benefit ratio is high if whole bowel irrigation is used to treat a nontoxic ingestion.

EQUIPMENT

- Nasogastric or enteral feeding tube, size 10 to 12 French
- Water-soluble lubricant
- Nasal decongestant and anesthetic
- Enteral feeding reservoir and tubing
- Polyethylene glycol electrolyte lavage solution (packets or reconstituted)
- Emesis basin
- Stethoscope
- Toomey syringe
- Intravenous extension tubing

The equipment required for whole bowel irrigation is readily available in most Emergency Departments. A small-bore, 10 to 12 French, nasogastric tube is sufficient for an adult or adolescent. An enteral feeding tube can be substituted if a sufficient flow rate can be ensured. A smaller tube is required in infants or very small children. Infants will tolerate an 8 French tube, and a 10 to 12 French tube is adequate beyond the first year.^{19,20}

Standard enteral feeding reservoirs and tubing are typically available as packaged kits. An enteral feeding or an enema bag with enteral feed tubing may be substituted. Enteral feeding pumps are not useful as the flow rate through the pump is typically inadequate to perform whole bowel irrigation effectively. Alternatively, an empty 1 L intravenous fluid bag with intravenous extension tubing can be used for the procedure.

Atomizer devices are usually not available in the Emergency Department. Many devices are available commercially. These are disposable devices that are single patient use (Figure 29-1 and Table 29-1). A popular device is the MAD line of mucosal atomizer devices (LMA North America, San Diego, CA). They make multiple devices for all topical needs.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Informed consent can be assumed in the case of suicidal ingestions. Inspect the nasal passages and oropharynx to rule out any anatomic abnormalities or obstruction that would preclude the passage of a nasogastric tube.

Place the patient in the upright or semi-upright position (Figure 78-1).²⁰ The supine and lateral decubitus positions are associated with a higher risk of pulmonary aspiration in comatose and mechanically ventilated patients.²¹⁻²⁴ It can be assumed

FIGURE 78-1. Setup required to perform whole bowel irrigation. IV, intravenous; NG, nasogastric.

that this positioning risk is similarly increased in patients undergoing whole bowel irrigation.

It is recommended that a cardiac monitor, noninvasive blood pressure cuff, and pulse oximeter be placed on the patient prior to performing whole bowel irrigation. This equipment may also be required based on the patient's physiologic status, the nature of the ingested or toxicant, and/or other underlying problems.

Choose the smallest diameter nasogastric or feeding tube that will allow adequate flow of polyethylene glycol electrolyte lavage solution into the stomach. Place all necessary equipment at the bedside and assembled prior to beginning the procedure.

Place a cuffed endotracheal tube prior to performing whole bowel irrigation in patients who are comatose, drowsy, obtunded, unconscious, or have an absent or impaired gag reflex. Strongly consider endotracheal intubation in any patient who has ingested a central nervous system depressant, tricyclic antidepressants, a sympathomimetic or other agent that may result in seizures, or any substances that can cause an altered mental status.

TECHNIQUE

Insert a nasogastric tube (Chapter 75). Measure the length of the nasogastric tube to be inserted. Place the tip of the nasogastric tube over the xiphoid process. Extend the tube over the anterior chest, lateral neck, behind the angle of the mandible, and to the tip of the nose. Mark this length with a permanent marker or a piece of surgical tape. Liberally lubricate the tip of the nasogastric tube. The application of a nasal anesthetic and decongestant is optional but can facilitate the passage of the nasogastric tube.

Gently insert the nasogastric tube into the naris. Advance the tube posteriorly along the nasal floor into the nasopharynx and through to the hypopharynx. Flexion of the neck may facilitate passage of the tube into the esophagus and avoid endotracheal insertion. The conscious and cooperative patient may be asked to swallow water through a straw or to swallow their saliva to facilitate passage of the tube. **Coughing, cyanosis, or stridor may indicate endotracheal passage and should prompt removal of the tube.** Gentle pressure and patient swallowing allow passage through the upper esophageal sphincter if significant resistance is met in the hypopharynx. **Do not force the nasogastric tube as misplacement may damage the**

larynx or perforate the pyriform sinus. Advance the nasogastric tube to the marked level. Confirm proper placement by the aspiration of gastric contents, by auscultation of insufflated air over the epigastrium using a 50 mL syringe, and/or by radiography. **Confirmation of intragastric placement must precede administration of any fluids through the nasogastric tube. A radiograph must be obtained prior to using the nasogastric tube if any question exists regarding its position.**

Administer 1 gm/kg in children or 50 to 100 gm in adults of activated charcoal via the nasogastric tube prior to administering the PEG-ELS if the suspected toxicant is adsorbed by activated charcoal. Instill the PEG-ELS through a setup such as that shown in **Figure 78-1**. Flow rates are dependent on the size of the patient. Begin instillation at an initial rate of 25 to 30 mL of PEG-ELS per kilogram per hour. Adults may tolerate more than 3 L of solution per hour. The rate may be adjusted somewhat to accommodate patient tolerance (e.g., abdominal distention or vomiting). Continue irrigation until the patient passes the ingested in the stool or until clear liquid rectal effluent is passed. Liquid stools will continue to be passed after discontinuing whole bowel irrigation. **Stop the irrigation if the patient vomits, develops an ileus, or if gastrointestinal perforation is suspected.**

ALTERNATIVE TECHNIQUES

Some Emergency Physicians may attempt whole bowel irrigation by offering the patient PEG-ELS to drink. This is rarely successful. Experience shows that whole bowel irrigation is ineffectively performed if a nasogastric tube is not placed. Even the most cooperative patient is unlikely to drink the solution at the required administration rate.

ASSESSMENT

Patient assessment must be continuous throughout the process of whole bowel irrigation. Mild abdominal distention, gassiness, and mild abdominal discomfort are common side effects and do not require the discontinuation of the infusion. Providers must be vigilant in monitoring the patient's bowel sounds. Hold the irrigation for 30 to 90 minutes and have the patient reassessed if bowel sounds cease or significant abdominal distention is noted. Resume the irrigation at a reduced rate if bowel sounds return, if the clinical status improves, and if the patient then tolerates the infusion. Significant electrolyte or osmotic shifts do not occur solely from whole bowel irrigation. Electrolytes may be monitored if otherwise indicated for the type of ingestion or for overall patient status.

Of great concern is vomiting with the risk of aspiration. **Maintain the patient's posture in the upright sitting or the semi-upright position to facilitate passage of irrigant solution into the small bowel and to protect against aspiration.** Discontinue whole bowel irrigation if the patient develops altered mental status or hemodynamic instability.

AFTERCARE

Patients who undergo whole bowel irrigation must all be admitted to the hospital for ongoing assessment of the intervention and the underlying ingestion of overdose. Intensive Care Unit or step-down monitoring will be required to ensure adequacy of the intervention and to monitor for complications of the ingestion or overdose. Delayed complications from whole bowel irrigation are unlikely once the procedure is completed.

COMPLICATIONS

Documented complications from whole bowel irrigation include pulmonary aspiration of the irrigant solution and/or ingested.^{16,17} This is especially concerning in the patient with an unprotected and

potentially compromised airway. An ileus and intestinal distension have been documented in a hypotensive patient receiving whole bowel irrigation.¹⁷

Osmotic and electrolyte abnormalities will not occur with the standard PEG-ELS solutions (e.g., Colyte, GoLYTELY, NuLYTELY). Complications of nasogastric tube placement are well described and can occur (Chapter 75). These are unlikely if proper technique is employed and can be minimized by use of the smallest effective diameter nasogastric tube.

SUMMARY

Whole bowel irrigation is a technique performed to speed gastrointestinal transit and decontaminate the gut after an acute toxic ingestion. Available reports suggest that whole bowel irrigation can decrease bioavailability of toxicants by two thirds in volunteers.^{3,6,15} It may be useful where activated charcoal is not expected to adequately bind ingestants (e.g., iron, lithium). Efficacy is still undefined in the setting of sustained-release or delayed-release preparations. Whole bowel irrigation is not the method of choice when more effective methods of gastrointestinal decontamination are possible (e.g., repetitive-dose activated charcoal for sustained-release theophylline). Whole bowel irrigation's role in managing the toxic ingestion remains limited.

Video Capsule Endoscopy for Gastrointestinal Bleeding

Eric S. Levy, Christopher J. Haines, and Grant Wei

INTRODUCTION

Gastrointestinal (GI) bleeding is a very common and potentially life-threatening pathology encountered by the Emergency Physician. It accounts for more than 400,000 hospital admissions each year, with mortality rates as high as 15%.¹ Expedient recognition, diagnosis, resuscitation, and treatment of the underlying etiology are essential in preventing morbidity and mortality. **The initial resuscitation to achieve hemostasis is paramount in the Emergency Department and often overshadows the search for the underlying etiology. The origin of the bleeding directs the algorithm for further management after stabilization.**

Since its introduction and approval by the U.S. Food and Drug Administration (FDA) approximately 15 years ago, video capsule endoscopy has been increasingly used. A pill-sized camera is swallowed, and real-time images of the GI tract are visualized. There have been more than two million video capsule endoscopies performed worldwide and thousands of research papers on its various aspects.² Video capsule endoscopy has shown significant promise and is quickly becoming one of the mainstays of medical management when compared to traditional methods of diagnosis and risk stratification.

This chapter introduces the use of video capsule endoscopy, a relatively novel method for the rapid diagnosis and risk stratification of acute GI bleeds. Video capsule endoscopy can be used in the Emergency Department. An Emergency Physician must be familiar with its potential complications and current limitations.

ANATOMY AND PATHOPHYSIOLOGY

The human GI system is divided into three main components derived from their embryological origins (i.e., the foregut, midgut, and hindgut). The foregut gives rise to the abdominal esophagus, the stomach, the proximal half of the duodenum, the liver, the gallbladder, and the pancreas. The midgut gives rise to the distal half of

the duodenum, the jejunum, the ileum, the cecum, the appendix, the ascending colon, and the proximal two-thirds of the transverse colon. The hindgut gives rise to the distal third of the transverse colon, the descending colon, the sigmoid colon, the rectum, and the proximal anal canal. Each of these regions is supplied by a specific branch of the aorta. It should be noted that the branches of these arteries frequently anastomose with each other and provide alternative routes of arterial supply.

The celiac trunk supplies the foregut derivatives. The celiac trunk divides into three branches. The common hepatic artery supplies the liver, gallbladder, stomach, duodenum, and pancreatic head and neck. The left gastric artery supplies the stomach and the esophagus. The splenic artery supplies the spleen, stomach, and the rest of the pancreas.

The superior mesenteric artery supplies the midgut derivatives. The superior mesenteric artery divides into many branches. The inferior pancreaticoduodenal artery supplies the head of the pancreas and the duodenum. The jejunal and ileal branches give rise to 15 to 18 intestinal branches. The middle colic artery supplies the transverse colon. The right colic artery supplies the ascending colon. The ileocolic artery supplies the ileum, cecum, appendix, and proximal ascending colon.

The inferior mesenteric artery supplies the hindgut derivatives. The inferior mesenteric artery divides into many branches. The left colic artery supplies the distal transverse colon and the descending colon. The sigmoid arteries supply the sigmoid colon. The superior rectal artery supplies the distal sigmoid colon and proximal rectum.

The venous drainage of the GI tract primarily flows through the hepatic portal system, which drains through the liver and its sinusoids into the hepatic vein and inferior vena cava. The portal vein is the main venous drainage system and is formed by the combination of the superior mesenteric vein and the splenic veins. The superior mesenteric vein drains portions of the foregut and all of the midgut. The splenic vein drains the spleen, pancreas, portions of the foregut, and all the hindgut derivatives via the inferior mesenteric vein. Similar to the arterial supply, the portal system has many anastomoses that prevent total occlusion should one of the major veins become obstructed. The most important of these anastomoses are in the lower esophagus (i.e., varices), the rectum and anal canal (i.e., hemorrhoids), and the paraumbilical region of the skin (i.e., caput medusae).³

Acute GI bleeding is clinically categorized into two general locations, upper and lower, that are separated by the ligament of Treitz. This ligament is a suspensory ligament classically attached to the distal segments of the duodenum or the duodenojejunal flexure, although considerable anatomic variation exists.⁴ Bleeding in the upper portion of the GI tract is defined by any lesion proximal to the ligament of Treitz, while a lower GI bleed occurs in any point distal to the ligament of Treitz. The designation of upper versus lower remains essential as the pathophysiology greatly varies, the secondary diagnostic modalities differ, and the therapeutic modalities differ. This chapter focuses primarily on upper GI bleeding, as this is where video capsule endoscopy has been shown to be most useful in the Emergency Department.

Upper bleeding sources account for up to 75% of cases of GI hemorrhage.⁵ Upper GI bleeding is further classified into variceal and nonvariceal (Table 79-1).⁶ **The most common source of nonvariceal bleeding is peptic ulcer disease, which accounts for 50% to 60% of cases.**⁷ The etiologies include infection with the *Helicobacter pylori* bacterium, the use of nonsteroidal anti-inflammatory drugs (NSAIDs), physiologic stress, and/or excess gastric acid.⁷ The *H. pylori* bacterium disrupts the superficial gastric mucosa and the cellular structure of the mucous membrane, causing increased susceptibility to acid damage. NSAIDs both worsen and predispose to ulceration of the GI tract by inhibition of prostaglandins, specifically cyclooxygenase-1 (COX-1), which plays a role in maintaining the integrity of

the mucosal lining.^{8,9} The following conditions have been shown to significantly correlate with the increased incidence of gastrin formation and peptic ulcer formation: physiologic stress, chronic ingestion of corrosive substances (e.g., caffeine, alcohol, and tobacco), coagulopathies, mechanical ventilation for more than 48 hours, traumatic brain injuries, traumatic spinal cord injuries, burn injuries, and glucocorticoid therapy.¹⁰ Excess gastric acid as the sole cause of a peptic ulcer is rare but is seen in patients with diseases like Zollinger-Ellison syndrome in which there is increased gastrin production.

Varices, or tortuous veins, originate from the portal system and account for 10% to 30% of all upper GI bleeds and anywhere from 50% to 90% of bleeds in cirrhotic patients.⁷ Bleeding variceal veins have a higher mortality rate than other sources, reaching greater than 20% mortality after 6 weeks despite advancements in medical management.⁷ Variceal bleeding can be divided into three main etiologies, all of which can cause bleeding from either the esophagus or the stomach. Prehepatic is when blood flow to the liver is obstructed. Posthepatic is when there is obstructed flow from the liver to the heart. Intrahepatic is the case with cirrhosis or other liver disease affecting hepatic sinusoidal blood flow.

Normal portal venous pressure ranges from 3 to 6 mmHg.³ Portal venous pressure increases to compensate for decreased blood flow and leads to pressures over 12 mmHg. The excessive pressure can cause the variceal veins to rupture and hemorrhage due to poor vascular wall strength. **It is imperative to distinguish variceal bleeding from other etiologies when the undifferentiated patient enters the Emergency Department due to the high mortality rate of variceal hemorrhages.** While rapidly recognizing and diagnosing the underlying etiology of an upper GI bleed is paramount in the grand scheme of medical management, it should be emphasized that timing is critical. **Priority should initially be given to the initial resuscitation.**

MANAGEMENT OF GI BLEEDING

Recent clinical guidelines have divided the timetable of upper GI bleeding management into the following four stages.^{11,12} The first stage is resuscitation, risk assessment, and pre-endoscopy

management. This includes the primary survey, hemodynamic stabilization, airway management, clinical scoring systems for risk stratification, the use of a nasogastric tube, capsule endoscopy or other means to determine the bleeding etiology, the use of initial antibiotics if a variceal bleed is suspected, the use of pre-endoscopic erythromycin to increase endoscopy diagnostic yield, and a proton pump inhibitor to increase the gastric pH to stabilize the clot. Second is endoscopic management within 24 hours of the patient's arrival. It is the direct visualization and stabilization of the lesion with the use of bipolar electrocoagulation, banding, sclerosant clips, or a heater probe. Third is the pharmacological management beyond the initial resuscitation measures. This involves longer term management such as continuous proton pump inhibitor infusions, treatment of suspected *H. pylori* infection, and the use of adjunctive therapies (e.g., albumin infusions, octreotide, vasopressin, or nitroglycerin). Last is the nonendoscopic and nonpharmacological management. This includes surveillance for the possibility of rebleeding and alternative management if bleeding remains refractory (e.g., interventional radiology or surgery).

The intricacies of each stage are beyond the scope of this chapter. **It is important to place video capsule endoscopy's role into the general context of emergency clinical management so that it can be used appropriately for both risk stratification and lesion detection.**

RISK STRATIFICATION

Aside from video capsule endoscopy, there are a couple of methods for initial risk stratification of the patient with an upper GI bleed. These include a thorough history and physical examination followed by clinical scoring systems (e.g., the Glasgow-Blatchford scale and the Rockall score).¹² Both of these can interconnect with laboratory tests and hemodynamic status to paint a clinical picture that would set the stage for further management beyond the endoscopic evaluation.

The history and physical examination are the foremost keys to differentiating etiologies and risk stratifying the upper GI bleed with or without the assistance of video capsule endoscopy. The history should be focused primarily on determining the patient's risk factors for hemorrhage. This includes a thorough review of the medication list for anticoagulants, NSAIDs, or steroids. The pertinent medical history is also important to obtain, especially a history of liver disease or other comorbidities that may predispose to complications with management. Examples are heart or lung disease predisposing to subsequent hypoxemia, cancers or leukemias and their treatments that hinder coagulation, or dementia or hepatic encephalopathy, which increases the risk of aspiration.¹³ Systemic signs and symptoms such as chest pain, shortness of breath, dizziness, syncope, decreased urine output, and altered mental status indicate decreased perfusion, suggest active or impending decompensation and the potential for shock, and require close monitoring of vital signs.¹³ Other relevant history includes previous abdominal or aortic surgeries, social history, presence and color of hematemesis, duration of symptoms, presence of dark tarry stools, presence of melena, and presence of hematochezia. For example, several episodes of nonbloody emesis followed by hematemesis make a Mallory-Weiss tear more likely, versus a sudden onset of copious hematemesis, which is more characteristic of a variceal bleed. The objective appearance of the blood may help determine if there is a significant risk of hemorrhage.^{13,14} For example, brown stool occultly positive is less likely to be a high hemorrhage risk or have hemodynamic significance compared to coffee-ground emesis and melena.

Clinical scoring systems are summarized in **Table 79-2**.^{15,16} They have been proposed for use in risk stratification and the need for urgent versus emergent endoscopy in nonvariceal bleeds.

TABLE 79-2 The Glasgow-Blatchford and Rockall Bleeding Scores

Glasgow-Blatchford score	Rockall score
<ul style="list-style-type: none"> Scores ≥ 6 are associated with a $> 50\%$ risk of requiring intervention 	<ul style="list-style-type: none"> Scores < 3 have a good prognosis Scores > 8 are associated with a high risk of mortality
Blood urea nitrogen	Age
6.5–8.0 = 2 points	$< 60 = 0$ points
8.0–10.0 = 3 points	60–79 = 1 point
10.0–25.0 = 4 points	$\geq 80 = 2$ points

The Glasgow-Blatchford scale aims to predict which patients will eventually require intervention in the form of blood transfusion, endoscopy, or surgery. The Rockall score predicts the probability of rebleeding and mortality. The Glasgow-Blatchford scale was found to be far superior in its respective goal compared to the Rockall score in terms of negative predictive value since none of the patients with a score of 0 on the Glasgow-Blatchford scale required endoscopy.^{17–20} Although a score of 0 on the Glasgow-Blatchford scale is highly indicative of a low-risk patient, any score above 0 is not as absolute, and therefore, the score generally requires supplementation with further testing.^{17–20}

Video capsule endoscopy has shown exciting promise in terms of risk stratification compared to clinical scoring systems.^{21,22} Video capsule endoscopy correctly identified 100% of the high- and low-risk patients on subsequent endoscopy. This confirmed the findings of a similar earlier pilot study, which predicted 100% of the high- and low-risk patients.²²

EARLY DETECTION OF BLEEDING ETIOLOGY

The use of a nasogastric tube (Chapter 75) with gastric lavage is currently one of the most commonly used techniques for the detection of upper GI bleeding. The benefit is three-fold. It removes potential aspirate in the case of frequent emesis. The removal of stomach contents may enhance visualization of the anatomy when an endoscopy is later performed.¹³ It also shows if a bleed is present and its characteristics (i.e., color, amount, and consistency).

A nasogastric lavage is somewhat invasive and often poorly tolerated. There are some significant limitations and potential complications. Studies have been done that have debunked some of the proposed benefits. There was a statistically significant correlation between a bloody lavage and high-risk lesions on subsequent endoscopy, with an odds ratio of 4.82 when compared to clear aspirate

and 2.8 when compared to coffee-ground aspirate.²³ However, the negative predictive value of clear aspirate was found to be inconsistent, with as many as 15% of patients having high-risk lesions on endoscopy. A study compared the use of erythromycin alone versus nasogastric lavage plus erythromycin as a means to prepare patients for subsequent endoscopy.²⁴ There was no significant difference in visualization or other outcomes between the two treatment groups. Erythromycin was also better tolerated and less invasive than nasogastric lavage. Based on this study, it is not necessary to rely on nasogastric lavage to improve visualization during endoscopy. Nasogastric lavage has not shown any significant improvement in the patient outcomes of mortality, hospital length of stay, or the need for subsequent transfusions.²⁵ The study concluded that nasogastric lavage is an invasive procedure that appears to have unclear clinical benefit and should not routinely be performed.

Video capsule endoscopy is much less invasive, better tolerated, and has been shown to have more consistent results than nasogastric aspirate and lavage in relatively small studies.²⁶ Nasogastric aspirate only identified 33% of bleeding lesions. Video capsule endoscopy identified 83% of bleeding lesions. Of the 17% of bleeding lesions missed, approximately one-third of missed bleeds were due to battery death before reaching the duodenum. This study also found that there was no significant difference between the identification of peptic or inflammatory lesions between capsule endoscopy and upper endoscopy, although upper endoscopy remains the gold standard.

The results from video capsule endoscopy are easy to interpret and do not require specialist training.^{27,28} Emergency Physician versus Gastroenterologist reads of video capsule endoscopy images from 25 subjects with upper GI bleeds found a 96% agreement between the two groups.²⁷ Additionally, video capsule endoscopy in these patients had an 88% sensitivity and 64% specificity for detection of fresh blood when compared to endoscopy. Another study by the same group further supported this result.²⁸ They compared Emergency Physicians and Gastroenterologists after a brief 10-minute training session, finding a sensitivity of 94% and a specificity of 87%.

Video capsule endoscopy is a cost-effective method for early low-risk bleeding detection and risk stratification when compared to the Glasgow-Blatchford scale (and all further testing it required), nasogastric lavage, and an admit-all strategy using standard decision analysis software.²⁹ Video capsule endoscopy had an average cost of \$5,691 compared to \$8,159 for the nasogastric tube, \$10,695 for risk stratification with subsequent tests, and \$22,584 for the admit-all strategy.

INDICATIONS

Video capsule endoscopy should be used within 6 hours after the patient's arrival in the Emergency Department with upper GI bleeding. Other indications not used in the Emergency Department

include the evaluation of celiac disease, Crohn's disease, iron deficient anemia, NSAID enteropathy, obscure bleeding, polyposis, portal hypertension, tumors, and unknown persistent abdominal pain.^{30,31}

CONTRAINDICATIONS

Video capsule endoscopy is generally considered to be safe and well-tolerated.³² **The presence of any signs of possible or impending airway compromise is an absolute contraindication to the use of video capsule endoscopy. Protection of the airway and initial resuscitation from blood loss always takes precedence over all further diagnostic studies.** In patients with altered mental status, dementia, or swallowing difficulties, aspiration of the capsule can occur. The inability to swallow for any reason is a contraindication to the procedure. Known dysphagia, esophageal strictures, esophageal webs, or disorders that may potentially hinder the passage of the capsule through the digestive tract (e.g., diverticula, fistulas, gastroparesis, small bowel obstruction, small bowel stenosis, and small bowel strictures) are other contraindications to video capsule endoscopy.³² Use caution with a history of prior abdominal surgery because patients can have adhesions or small bowel narrowing. Magnetic resonance imaging cannot be performed until the capsule is evacuated from the GI tract.

It has also been proposed that patients with cardiac pacemakers or defibrillators should not be considered candidates for video capsule endoscopy due to potential radiofrequency interference.^{32,33} This recommendation is found on the FDA video capsule package insert. However, multiple studies have shown that video capsule endoscopy can be used safely with pacemakers and defibrillators, and therefore, these are a relative contraindications.³³⁻³⁸ Consult a Gastroenterologist before performing video capsule endoscopy on these patients.

Pregnancy is considered a relative contraindication to the use of video capsule endoscopy. This is due to the increased risk of impaction requiring surgical intervention and thus potential harm to the fetus.³² There have been case reports of video capsule endoscopy being successfully used in pregnant women.^{39,40} The exact risk to the fetus is currently unclear. Consult a Gastroenterologist before performing video capsule endoscopy on these patients.

EQUIPMENT

- Wireless video capsule (Table 79-3, Figures 79-1 and 79-2)
- Software for the video capsule
- Sensing system (Figure 79-3)
- Sensing pads
- Data recorder with a battery pack (Figure 79-4)

- Compatible handheld sensing system that allows real-time image viewing
- Computer capable of running proprietary software for image review and interpretation

There are many video capsules on the market (Table 79-3). They differ in regard to their battery life, field of view, dimensions, image requisition, and optics.^{41,42} Most video capsules move passively through the GI system. Research is well under way for external magnet-guided and self-propelled capsules (Figure 79-5).⁴³ The capsule used by most of the current studies is the PillCam ESO2 (Given Imaging, Yokne'am Illit, Israel). The PillCam measures 11.4 mm by

FIGURE 79-3. The PillCam sensing belt. (Photo courtesy of Given Imaging.)

26.4 mm, approximately the size of a large multivitamin pill, and weighs approximately 3 gm.^{27,44} Each video capsule has similar components including a disposable plastic exterior with a complementary high-resolution charge-coupled device image capture system or metal oxide semiconductor, white light-emitting illumination sources, transmitter, a short focal length capability, and an internal battery.⁴⁵ The video capsule can detect lesions as small as 0.1 mm in diameter. On each end of the capsule, the PillCam ESO2 has an optical dome capable of capturing approximately 18 frames per second, has a wider angle view of approximately 169°, and has more advanced optics (i.e., three lenses) than most other small and large bowel capsules.⁴⁴ The battery life of this capsule is significantly lower than other capsules, lasting only for approximately 30 minutes. The data from the lenses is transmitted via ultra-high-frequency band radio telemetry through the sensory pads and belt to the data recorder, which then transmits the date to the computer or handheld device.⁴⁵ Some of the software marks images to be reviewed that contain blood.

PATIENT PREPARATION

The patient should ideally be fasting for at least 2 hours prior to a video capsule endoscopy procedure.⁴⁶ Conditions in the Emergency Department are often less than ideal, and few, if any, patients are able to be prepped appropriately. The studies evaluating the success of video capsule endoscopy discussed earlier took this aspect into account, and all results were in patients who lacked the ideal preparation. **The main preparation required prior to this procedure is initial stabilization of airway, breathing, and circulation as well as assessing for and ruling out any significant contraindications.**

The patient and/or their representative must be informed of the procedure, including its risks and benefits. Obtain an informed consent for the video capsule endoscopy procedure. No anesthesia or sedation is required. Obtain plain radiographs of the abdomen to make sure there is no bowel obstruction prior to the procedure.

FIGURE 79-2. Schematic of a video capsule. **A.** External view. **B.** Schematic cross-section and elements (1 – optical dome, 2 – lens holder, 3 – short focal aspheric lens, 4 – white LEDs, 5 – CMOS imager, 6 – batteries, 7 – ASIC transmitter, 8 – antenna.) (Used with permission from reference 40.)

FIGURE 79-4. The PillCam data recorder. (Photo courtesy of Given Imaging.)

Attach the sensing pads to the patient over the midline of the upper sternum, over the midline of the lower sternum, and in the left upper quadrant of the abdomen over the anatomical location of the stomach (**Figure 79-6**).²⁷ Attach the wiring to the data recorder either around the patient's waist or over the patient's shoulder.²⁷

TECHNIQUE

Turn on the recorders. Activate (i.e., turn on) the video capsule when the procedure is ready to begin. Instruct the patient to drink approximately 100 mL of water while standing followed by the ingestion of the activated capsule in the supine position with a 10 mL sip of water through a syringe or straw.⁴⁵ The ingestion protocol is then followed. This involves 2 minutes of recording with the patient supine, followed by 2 minutes with the head of the bed raised to 30° degrees, an additional minute at 60°, and finally, 15 minutes in the upright position to maximize data capture time.⁴⁵ Alternatively, the capsule can be ingested with a sip of water in the prone position. After 2 minutes of recording in this position, place the patient in an upright seated position while the rest of the images are recorded.²² If the capsule remains in the stomach for more than 15 minutes, the patient can be placed in the right lateral decubitus position to facilitate passage into the duodenum.²² The images are then viewed on either the computer or handheld device.

ASSESSMENT

Review the images on either the computer or handheld device (**Figure 79-7**).⁴⁷ Look for bleeding sites (active or inactive), masses, mucosal damage, petechia, red spots, tumors, ulcerations, or any other abnormalities.

AFTERCARE

Minimal aftercare is required. After the 30 minute of recording, the capsule automatically deactivates and is passed through the intestine via peristalsis, leading to the eventual natural evacuation.³⁶

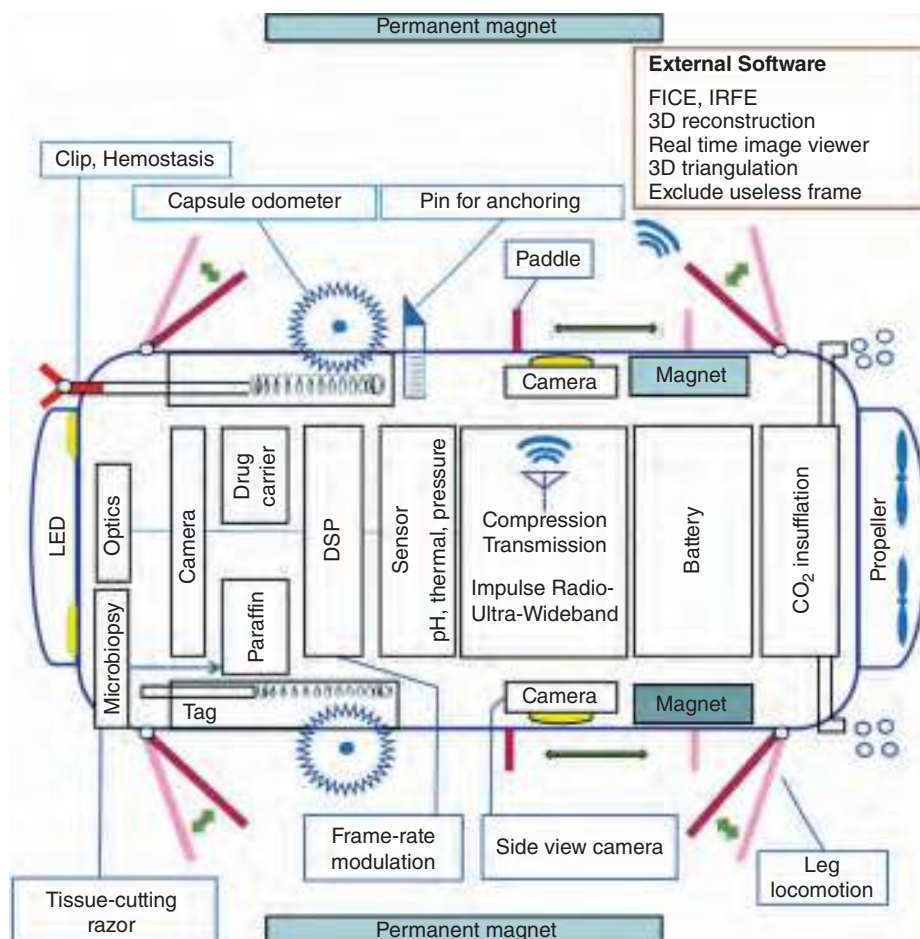

FIGURE 79-5. Schematic of a magnetically guided video endoscope camera. (Used with permission from reference 42.)

FIGURE 79-6. Sensing pad placement. (Photo used with permission from reference 27.)

However, postprocedural follow-up is often recommended to ensure appropriate passage of the capsule and to address any potential complications.

COMPLICATIONS

Video capsule endoscopy is usually well tolerated with a very low complication rate. However, as with any procedure, complications do exist. **Video capsule aspiration leading to airway compromise with or without obstructive pneumonitis is always a possibility and must be carefully monitored during ingestion.**⁴⁸ Bronchoscopy

will be required for removal of the video capsule.^{48,49} The risk of aspiration can be decreased by ruling out significant contraindications and proper patient positioning during the video capsule ingestion.

The most common postingestion complication is capsule retention. This occurs in approximately 1.4% of cases and is the stem from which a majority of other potential complications can occur.⁴⁸ The reasons for retention are extensive but mainly involve undiagnosed inflammatory bowel disease (most common), gastroparesis, neoplasms, NSAID-induced enteropathy, postabdominal radiation, postsurgical stenosis, small bowel strictures, tuberculosis, or bowel ischemia.⁵⁰ While the majority of these patients remain asymptomatic, a very low percentage develop subsequent complications.⁴⁸ In a retrospective study of over 1000 video capsule endoscopies, none of the patients had significant symptoms as a result of capsule retention.⁵¹

Several steps can be taken to minimize retention risk. This includes an adequate initial history for risk factors, motility agents, anti-inflammatories, or colonoscopy preparation fluids to help promote spontaneous passage, nasogastric tube insertion for bowel decompression, and close monitoring with serial abdominal plain films to ensure progression.⁵⁰⁻⁵³ If conservative measures do not lead to spontaneous passage, either endoscopic or surgical removal should be considered depending on the retained location.

There have been a few documented case reports of rare complications from capsule retention, the most serious of which is bowel perforation requiring immediate surgical intervention, although preexisting inflammatory bowel disease seems to be the most likely underlying culprit.^{54,55} An even rarer complication is the development of acute appendicitis from capsule retention, which is managed by appendectomy.^{56,57}

LIMITATIONS OF VIDEO CAPSULE ENDOSCOPY

Although the technology behind capsule endoscopy is exponentially advancing, current models still have several limitations, the most noticeable of which is the operator's inability to control the

FIGURE 79-7. Examples of the PillCam images. **A.** Petechiae and red spots. **B.** Petechiae and red spots. **C.** Mucosal erosion. **D.** Mucosal erosion. **E.** Ulceration. **F.** Ulceration. (Used with permission from reference 47.)

video capsule maneuvers throughout the GI tract.² As a result, the quality and location of the images obtained are at the mercy of capsule visibility and the angle of the capsule, both of which are difficult to predict. This can be somewhat alleviated by proper patient positioning during ingestion but remains a potential obstacle. The esophageal capsule models used in the emergent setting have a typical battery life of only 30 minutes. This may limit the capsule's ability to reach the duodenum prior to loss of battery power.³² Unlike upper endoscopy, current capsule models remain solely diagnostic without any therapeutic ability. The video capsule cannot immediately address a high-risk bleeding lesion if detected. Despite these limitations, video capsules are continuously improving and may one day show significant improvement in these areas.

SUMMARY

Upper GI bleeding remains a high-stakes pathology with which the well-trained Emergency Physician must be proficient. The approach to each of these patients must remain systematic, with priority given to initial resuscitation before any further intervention is considered. After the initial resuscitation, video capsule endoscopy has emerged as one of the most promising diagnostic tools for risk stratification as well as detection of upper GI bleeding etiology. Despite its current limitations, it has taken significant strides toward acceptance in the Emergency Department.

Video capsule endoscopy should always be considered in the context of the overall clinical picture. Further studies with much greater sample sizes are still warranted to confirm the initial findings and compare this treatment with alternative methods. Video capsule endoscopy should be used in conjunction with the other established methods in comprehensive clinical decision making.

Each year, the technology for video capsule endoscopy progresses. This has the potential of making current limitations ephemeral. Video capsule endoscopy could become one of the mainstays in the medical management of upper GI bleeding in the Emergency Department.

INTRODUCTION

Most foreign bodies (i.e., 90%) that are ingested enter the gastrointestinal tract, while 10% enter the tracheobronchial tree.¹ Approximately 1500 people die annually in the United States from ingested foreign bodies in the upper gastrointestinal tract.² Most objects (i.e., 80% to 90%) usually pass spontaneously, but approximately 10% to 20% must be removed endoscopically.³ Approximately 1% require surgical removal.⁴ Approximately 80% of esophageal foreign bodies occur in children, followed by edentulous adults, prisoners, and psychiatric patients.⁵ Recurrent episodes of foreign body ingestion occur in 5% to 10% of patients, especially prisoners and psychiatric patients.¹

The presentations are best divided into accidental and deliberate ingestions.^{1,2,4-7} The accidental ingestion patient is usually cooperative and has a single foreign body. The deliberate ingestion patient is often uncooperative, the foreign bodies are multiple, and the foreign bodies are often unusual. It is important to identify such individuals at their initial presentation since foreign body removal is usually performed under conscious sedation or general anesthesia.

The patient's history is the most important part of the diagnostic evaluation.^{4,8} The identity of the object ingested is usually known to the patient. **Persistent odynophagia, dysphagia, or foreign body sensation may indicate the presence of an esophageal foreign body despite negative radiographic results. A high index of suspicion must be maintained in younger children and mentally retarded adults.**⁹⁻¹¹ Patients with a history of eosinophilic esophagitis have a higher incidence of food impaction and higher risk of perforation associated with interventions.¹²

The physical examination is most likely negative unless complications are present. Note any stridor, wheezing, signs of consolidation, and the absence of breath sounds. Subcutaneous emphysema in the neck or chest indicates perforation of the esophagus or the stomach. **The most common sites for a foreign body to get trapped are where the esophagus is narrow (i.e., at the cricopharyngeus muscle, where the aortic arch crosses the esophagus, and at the gastroesophageal junction).**

Radiographic evaluation is often helpful in the evaluation of an esophageal foreign body (**Figure 80-1**).^{4-7,13-16} Obtain plain radiographs of the neck and chest in the posteroanterior and lateral positions. Evaluate the radiographs for the presence of a foreign body in all planes. Air in the subcutaneous tissues, mediastinum, and/or beneath the diaphragm is indicative of a perforation. Barium studies are undesirable in patients with a food bolus impaction and obscure endoscopic visualization. Esophagrams performed using a minimal amount of thin barium may be necessary in situations where the foreign body is made of wood, thin metals, aluminum can top, and plastics. **Meglumine diatrizoate (Gastrografin) is contraindicated in food bolus impactions because it is highly hypertonic and can lead to severe chemical pneumonitis if aspirated into the lungs.**⁶ Toothpicks, wood, and fish bones may not be seen on radiographs. Food or meat bolus impaction may not be evident radiographically unless it contains bony tissue. **Failure to locate an object on radiologic examination should not rule out its presence.** Computed tomography may be useful, especially in cases where the foreign body could not be detected as it may have become embedded in or penetrated the esophageal wall.^{16,17}

The lateral soft tissue of the neck can be particularly helpful in evaluating for an esophageal foreign body.^{13,14} The radiograph can be obtained at the bedside in ill patients, is inexpensive and quick to obtain, and may show soft signs of an esophageal foreign body (**Figure 80-1**). A single air column is normally seen (**Figure 80-1A**). A double air column represents air in the esophagus and the airway (**Figures 80-1B and 80-1C**). An air-fluid level may be seen in the esophagus.

Endoscopy is important for both the diagnosis and possible removal of an esophageal foreign body.^{7,18-20} Extraction with the flexible endoscope is successful in 84% to 98% of cases with no associated complications.^{21,22} Consider an Otorhinolaryngology consultation if foreign bodies are at or above the cricopharyngeus level. Success is more likely and complications are minimized with proper patient preparation.

INDICATIONS

Esophageal foreign body extraction is required in a minority of patients. Most foreign bodies will pass spontaneously into the stomach. The indications for removal depend on the type of foreign body

FIGURE 80-1. Lateral soft tissue radiographs of the neck. **A.** Normal. **B.** Impacted food bolus 30 cm from the incisors. **C.** Outline of the double air column. **D.** A button battery (A) versus a coin (B). **E.** Safety pin. (Photos used with permission of reference 13 and 14.)

and whether it impacts in the esophagus. Remove sharp objects impacted above the cricopharyngeus under direct vision using a laryngoscope to elevate the soft tissues and forceps (i.e., Boedecker, Magill, or Tylke) to grasp it.

Meat boluses are commonly impacted in the esophagus. Patients will swallow large pieces that may or may not be well chewed. **Impaction of a meat bolus, or another foreign body, at or just below the cricopharyngeus muscle with tracheal compression and resultant respiratory obstruction is a true emergency.** The Heimlich maneuver may be lifesaving in this situation.²³ **Immediately intubate the patient orotracheally or perform a cricothyroidotomy if the Heimlich maneuver is unsuccessful.** Early removal of a meat bolus impaction is recommended, even when the bolus is in the distal third of the esophagus. Delays in extraction allow the food to soften and make extraction more difficult. The administration of glucagon intravenously may lead to esophageal relaxation and facilitate spontaneous passage of the food bolus to the stomach. It must be endoscopically removed if glucagon fails.

Blunt and round objects may become impacted in the esophagus. **Earlier removal is necessary if a blunt object is impacted higher in the esophagus with associated sialorrhea and the potential for pulmonary aspiration.** Esophageal obstruction at lower levels requires prompt, but not emergent, treatment. Most rounded objects in the lower third of the esophagus will often pass spontaneously into the stomach. A 12 hour period of observation is permissible in this situation.²⁴ It is common for sharp, pointed, and elongated objects to become impacted in the esophagus. Toothpicks, open safety pins, nails, and chicken bones are associated with up to a 35% incidence of esophageal perforation and should be removed.^{25,26} Toothpicks should be removed promptly from the esophagus or stomach even if they are not impacted because they are prone to penetration of the gastrointestinal wall. Toothpicks may migrate into surrounding structures and lead to serious complications.²⁵

Numerous other objects can become impacted in the esophagus. Elongated, narrow foreign bodies such as stiff wires are prone to penetration and perforation of the esophageal wall. They should be removed even if they passed through the esophagus and into the stomach. These objects may become trapped by the retroperitoneally fixed angles of the duodenum and eventually result in perforation. Plastic bag clips, although not sharp and pointed, should be removed before they pass from the esophagus into the stomach and through the pylorus. They have claws that can attach to the small bowel mucosa, leading to ulceration, stricture formation, and bleeding.²⁷ Toxic foreign bodies (e.g., button batteries) that become impacted in the esophagus should be removed promptly to prevent perforation and systemic toxicity.

CONTRAINDICATIONS

There are no absolute contraindications to the removal of an esophageal foreign body. Treat life-threatening and limb-threatening injuries prior to esophageal foreign body removal. Evaluate and support the patient's airway, breathing, and circulation prior to removing the foreign body.

EQUIPMENT

- Flexible upper gastrointestinal endoscope
- Rigid gastroscope
- Through-the-scope balloon
- Steigmann-Goff friction-fit adaptor of the esophageal variceal rubber banding ligating kit
- Glucagon
- 44 French Maloney rubber dilator
- Lubricant gel

- Endoscopic overtube, for use with sharp or pointed foreign bodies
- Soft latex protector hood for the flexible scope
- Rat-tooth or alligator forceps
- Retrieval nets or Dormia baskets
- Polypectomy snares
- Laryngoscope
- Laryngoscope blades, Miller and Macintosh of various sizes
- Airway forceps (i.e., Boedecker, Magill, or Tylke)
- Curved clamp
- Medications for procedural sedation (Chapter 159)
- Cardiac monitor
- Pulse oximetry
- Supplemental oxygen
- Foley catheters, 14 to 16 French
- Topical anesthetic spray
- Water-soluble contrast material
- 5 mL syringe
- Fluoroscopy machine, optional

PATIENT PREPARATION

Obtain a duplicate sample of the ingested foreign body if possible. Manipulate the duplicate object with available foreign body forceps and snares. Determine which instrument is best suited to grasping the foreign body. Instruments that are most useful include alligator and rat-toothed forceps, endoscopic overtubes, polypectomy snares, and Dormia baskets.

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure, and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

The timing of the endoscopic intervention is important (**Table 80-1**). It depends on the clinical condition of the patient, the nature of the

TABLE 80-1 Timing of Endoscopy for Foreign Bodies in the Esophagus

Nonurgent endoscopy
Coin in the esophagus of an asymptomatic patient
Coins and batteries in the stomach of an asymptomatic patient
Foreign body with a diameter of > 2.5 cm in the stomach
Foreign body longer than 3 cm in infants and young children
Foreign body longer than 5 cm in older children, adolescents, and adults
Urgent endoscopy
Absorptive foreign bodies
Batteries in stomach if battery is > 20 mm diameter
Esophageal food impaction not causing a complete obstruction
Esophageal foreign bodies that are not sharp
Foreign body longer than 6 cm in adolescents and adults
Multiple magnets
Sharp foreign body in the stomach if asymptomatic
Emergent endoscopy
Battery in the esophagus
Battery in the stomach if symptomatic
Complete esophageal obstruction
Magnets in the esophagus
Magnets in the stomach if symptomatic
Sharp foreign body in the esophagus
Sharp foreign body in the stomach if symptomatic

foreign body, the risk of aspiration, or the risk of additional complications (e.g., obstruction or perforation). Patients who have difficulty managing their secretions or who ingested sharp-pointed objects or disk batteries that localized to the esophagus should undergo emergent endoscopy. Patients who ingested blunt foreign bodies that are in the esophagus without complete esophageal obstruction will require urgent endoscopy. Urgent endoscopic removal is required for magnets, objects < 6 cm in length at or above the proximal duodenum, and sharp or pointed objects in the stomach or duodenum. Objects with a diameter > 2.5 cm in the stomach will require nonurgent endoscopy. Coins located in the esophagus may be monitored for 12 to 24 hours prior to endoscopic removal if the patient is free of symptoms.²⁸

The management of ingested foreign body requires assessment of the patient's airway and ventilation status. Most esophageal foreign bodies may be removed under procedural sedation. Airway protection may require endotracheal intubation and general anesthesia, especially when the foreign body is difficult to remove or located in the proximal esophagus. Endoscopic overtubes facilitate the frequent passage of the scope and protect the airways. Endoscopic overtubes protect the esophageal mucosa from injury upon the removal of sharp objects.^{4,28}

Apply monitors for electrocardiogram, blood pressure, and pulse oximetry along with an intravenous line for the administration of drugs. Administer supplemental oxygen by nasal cannula or "blow-by." The patient may be in a sitting, semirecumbent, supine, or left semilateral position. The sitting position will displace redundant pharyngeal tissue anteriorly and open the pharyngeal space by gravity in morbidly obese patients. Maneuvers performed by an assistant (e.g., the jaw thrust or pulling the tongue forward with a cotton swab) can help to move the pharyngeal soft tissues anteriorly and allow increased maneuverability.

Instrumentation may cause the patient to produce copious secretions. This makes removal of the foreign body extremely difficult. Consider administering 0.3 to 0.4 mg of glycopyrrolate. Administer this potent antisialagogue intravenously at least 10 minutes before or intramuscularly 30 minutes before the foreign body is removed. Atropine is often more readily available in the Emergency Department than glycopyrrolate. It can be administered in a dose of 0.5 mg intravenously at least 10 minutes before foreign body removal. The only disadvantages of atropine are that it crosses the blood-brain barrier and can cause central nervous system effects, whereas glycopyrrolate does not. Refer to Chapter 12 for a more complete discussion of these two antisialagogues.

Sedation can be extremely beneficial in gaining the patient's cooperation during the foreign body removal. **Sedative drugs, if used at all, should be judiciously titrated to the desired effect with continual assessment of the patient's level of consciousness while avoiding respiratory depression.** Ketamine given in small doses (e.g., 0.5 to 1 mg/kg) and titrating to the desired level of sedation has the advantage of producing minimal respiratory depression and may be preferable to opioids in some cases. Refer to Chapter 12 for a more complete discussion of the pharmacologic adjuncts to intubation. **Avoid sedation if the patient has a tenuous airway, labored respirations, or a distended abdomen or is vomiting.**

It remains an unresolved controversy whether to abolish the laryngeal reflexes of a patient considered to have a "full stomach." The Emergency Physician must weigh the risk of abolishing the laryngeal reflexes and rendering the patient potentially vulnerable to aspiration versus leaving the laryngeal reflexes intact. Instrumentation in patients with an intact gag reflex can induce vomiting.

The oral cavity, oropharynx, and supraglottic larynx can be anesthetized. Place a tongue blade on the patient's tongue and apply topical anesthetic spray (**Figure 28-10**). Benzocaine or lidocaine spray

will usually provide effective anesthesia for the posterior pharynx within 30 seconds. They can be administered from a commercially available spray container or using an atomizer device (**Figure 28-3 and Table 28-3**). There are reports of methemoglobinemia from the overzealous use of benzocaine. Limit its use to several short sprays.

Alternatively, the patient can swish 2% viscous lidocaine in their mouth for several minutes to provide effective anesthesia. One of the most effective methods of blocking the glossopharyngeal nerve is the "lollypop method." Create a lollypop by soaking sterile gauze in lidocaine ointment and taping it to a tongue depressor. Place the lidocaine lollypop into the patient's posterior mouth while setting up for the fiberoptic foreign body removal. Advance the lollypop 1 cm every 2 minutes until the patient's posterior pharynx is completely anesthetized.

Place a suction catheter into the oropharynx. This will clear the airway of secretions and blood that can impair the visual image. It will also determine the adequacy of the topical anesthesia for preventing coughing and gagging.

TECHNIQUES

GENERAL PRINCIPLES

The flexible upper gastrointestinal endoscope (Figure 80-2A) is similar to a flexible bronchoscope (Chapter 28). It is inserted under direct visualization to avoid inadvertently striking the foreign body and further impacting it or causing it to penetrate the esophageal wall. Blunt foreign bodies (e.g., button batteries and coins) can be securely grasped with forceps or a snare (**Figure 80-3**). **A firm grasp on the foreign body is required before withdrawal is attempted.** The foreign body may otherwise become dislodged as it is withdrawn through points of anatomic narrowing. This can result in aspiration of the foreign body. An overtube should be used if multiple insertions and withdrawals of the endoscope are needed (**Figure 80-2B**). Pointed foreign bodies should be withdrawn with the point trailing to avoid perforating any structures (**Figure 80-4**). Grasp objects with sharp edges (e.g., razor blades) and extract them through an overtube to prevent secondary injury (**Figure 80-5**). Elongated foreign bodies such as wires or pens should be grasped with a snare close to the cephalad end of the object so it can align itself with the long axis of the esophagus during withdrawal. Foreign bodies that penetrate the mucosa can be safely extracted with the endoscope if frank perforation or vascular penetration has not occurred.

FOOD IMPACTIONS

ENDOSCOPY

Food impactions are more likely to occur in the distal esophagus. There is no need for barium studies because it will obscure visualization during endoscopy if the patient is symptomatic. **Endoscopic intervention should be carried out immediately to prevent aspiration if the patient is salivating and unable to handle oral secretions. The impacted food bolus should not remain in the esophagus for more than 12 hours. The risk of complications increases significantly the longer the foreign body is in the esophagus.**

Underlying esophageal disease is found in 65% to 97% of adults presenting with an esophageal food impaction.^{21,29,30} **Endoscopic removal is the procedure of choice if a food bolus does not pass spontaneously or after an unsuccessful trial of gas-forming agents, glucagon, nifedipine, or nitroglycerine (Figure 80-6).** Remove the entire bolus slowly under direct visualization. Snugly pull the grasping instrument with the food bolus against the tip

A

of the endoscope when the endoscope is just below the cricopharyngeus muscle. Extend the patient's head and quickly remove the endoscope.³¹

A piecemeal approach can be accomplished with several passages of the endoscope through an overtube if the food bolus is soft.³² The overtube will facilitate reinsertion of the endoscope. Insert a 44 French Maloney rubber dilator into the esophagus and proximal to the foreign body. Pass the overtube, lubricated internally and externally, over the Maloney dilator. Remove the Maloney dilator. Introduce the flexible endoscope through the overtube.

Another method is the push technique. It has been useful in dealing with an impacted food bolus.²² A small-caliber flexible endoscope may be used to bypass the food bolus and evaluate the area distal to the obstruction. If the endoscope passes into the stomach successfully, pull it back until it is just proximal to the food bolus. Use the endoscope to gently push the food bolus into the stomach. It is preferable to push from the right side of the food bolus rather than straight through the middle. The gastroesophageal junction usually takes a left turn as it enters a hiatal hernia. The presence of

FIGURE 80-3. Endoscopic foreign body instruments. Top row: snare, basket, and multiarm grasper. Bottom row: grasper, a traumatic grasper, and Roth net. (Photo used with permission from Callahan CJ: Endoscopic foreign body removal. *Today's Veterinary Practice* 2015;5(6):77-83, www.veteriankey.com.)

a bone spicule should always be considered, whether the meat bolus is being extracted or pushed into the stomach.

A newer technique is accomplished by attaching the Steigmann-Goff friction-fit adaptor of the esophageal variceal rubber banding ligating kit to the tip of the endoscope.³³ The tip of the endoscope is

FIGURE 80-4. Endoscopic removal of a sharp foreign body. The pointy end is trailing for the removal so it does not perforate soft tissues. (Photo courtesy of Olympus Endoscopy.)

FIGURE 80-5. Endoscopic removal of a sharp foreign body through an overtube. **A.** Grasping the foreign body. **B.** Pulling the foreign body into the overtube. **C.** Removal of the foreign body. (Photo used with permission from www.veteriankey.com.)

replaced with a screw-on drum from the variceal ligation kit. Place an esophageal overtube proximal to the food bolus. Insert the endoscope through the overtube.³⁴⁻³⁷ A Roth retrieval net may be passed through the endoscope to retrieve food from the esophagus to avoid the risk of dropping the food in the trachea.^{38,39}

A last resort approach is the use of an Nd:YAG laser to burn an opening in the center of an impacted meat bolus. This method is expensive and carries a high risk of complications.⁴⁰ Consider rigid endoscopy under general anesthesia if a food impaction of the esophagus cannot successfully be removed using the flexible endoscope.⁴¹

■ GAS-FORMING AGENTS

Gas-forming agents can be used to relieve a distal esophageal food impaction. They are occasionally used to relieve a food impaction in the proximal and middle thirds of the esophagus. These agents

produce carbon dioxide gas that distends the esophagus, relaxes the lower esophageal sphincter, and “pushes” the food bolus through the gastroesophageal junction with the aid of esophageal peristalsis. Gas-forming agents may be used in conjunction with glucagon, nifedipine, or nitroglycerine to help relieve the impacted food bolus. Complications associated with gas-forming agents include aspiration, vomiting, forceful vomiting, and esophageal perforation due to distention and/or vomiting. Many physicians do not use these agents due to the risk of perforation.

Three classes of gas-forming agents have been used. Commonly used are commercially available agents that are used by Radiologists for upper gastrointestinal contrast studies. A mixture of tartaric acid (1.5 to 3.0 gm in 15 mL H₂O) immediately followed by sodium bicarbonate (1.5 to 3.0 gm in 15 mL H₂O) has been successfully used. Another agent is carbonated soda pop.

■ GLUCAGON

A trial of intravenous glucagon before endoscopic therapy is a reasonable approach.^{42,43} It may disimpact a food bolus in the distal esophagus and allow it to pass into the stomach. Glucagon relaxes the smooth muscle of the lower esophagus and decreases lower-esophageal sphincter tone. Glucagon relaxes the esophageal smooth muscle within 1 minute of intravenous injection, and its effects last approximately 20 to 25 minutes. Glucagon has no effect on the proximal third of the esophagus that is composed of skeletal muscle. It has a minimal effect on the middle third of the esophagus that is composed of both skeletal and smooth muscle. Glucagon has an overall success rate of ≤ 50%. Glucagon has been also combined with gas-forming agents to enhance esophageal clearance.

The dose of glucagon is 0.03 to 0.1 mg/kg intravenously with a maximum dose of 1 mg in children and 2 mg in adults. It should be administered over 1 to 2 minutes. **It is recommended to give a test dose (e.g., one-tenth of the full dose) and observe the patient for 5 minutes for signs of hypersensitivity or hypotension before giving the full dose.** Have the patient take one to two sips of water after the administration of glucagon to stimulate lower esophageal

FIGURE 80-6. Endoscopic removal of a food bolus. (Photo courtesy of Olympus Endoscopy.)

peristalsis. Administer a second dose of glucagon if the food bolus impaction is not relieved within 10 to 20 minutes.

Glucagon is a relatively safe medication.^{42,43} It should not be administered to patients with known hypersensitivity to glucagon, esophageal fibrosis, esophageal rings, esophageal strictures, insulinomas, pheochromocytomas, sharp or irregular foreign bodies, or Zollinger-Ellison syndrome. Exogenous glucagon stimulates the release of catecholamines. It can stimulate a pheochromocytoma to release catecholamines, resulting in marked hypertension and tachycardia. The hypertension can be controlled using 5 to 10 mg of intravenous phentolamine. Glucagon's hyperglycemic effect can cause an insulinoma to release insulin and cause subsequent hypoglycemia.

Common complications associated with glucagon include nausea, vomiting, transient hyperglycemia, allergic reactions, tachycardia, and hypertension. Glucagon is a polypeptide hormone synthesized in nonpathogenic *Escherichia coli* that have been genetically altered. This is the basis of the allergic or hypersensitivity reactions. A transient rise in blood pressure and heart rate is often seen after administration of glucagon. Patients taking beta-blockers may be more susceptible to transient hypertension and tachycardia. These side effects are short-lived as the half-life of glucagon is 8 to 18 minutes.

■ NIFEDIPINE

Nifedipine is a calcium channel blocker that decreases lower esophageal sphincter tone. It is sometimes administered to allow an impacted food bolus to pass into the stomach. It should not be administered if the patient has an allergy to calcium channel blockers, has hypotension, or has ingested a sharp or irregular-shaped foreign body. With a single dose, nifedipine has few side effects. These are usually minimal (e.g., dizziness, flushing, headache, hypotension, lightheadedness, muscle cramps, nausea, nervousness, and palpitations) and do not preclude its use.

The most significant effect of nifedipine is hypotension that may last 6 to 8 hours. Some patients will have a significant hypotensive response to nifedipine, and there is no way to predict which patients will be affected. For these reasons, many physicians will not use nifedipine in the elderly or in patients with a history of cardiac disease, coronary artery disease, stroke, or who are concurrently taking antihypertensive medications.

The typical dose is 10 mg of oral nifedipine. The medication may be chewed and then held in the mouth and subsequently swallowed. Alternatively, open the capsule, place the medicine sublingually, and have the patient hold it in their mouth and then swallow the dissolved nifedipine. Attempt another technique if the food bolus does not pass with one dose of nifedipine.

■ NITROGLYCERINE

Sublingual nitroglycerine (i.e., 0.3, 0.4, or 0.5 mg) relaxes vascular smooth muscle and the smooth muscle contained within the middle and distal thirds of the esophagus. The use of sublingual nitroglycerine may allow the esophagus to dilate enough so that a food bolus can pass into the stomach.

Nitroglycerine should not be administered if the patient is hypotensive or has ingested a sharp or irregular-shaped foreign body. It should also not be administered if the patient is taking prescription medications for erectile dysfunction (e.g., vardenafil [Levitra], tadalafil [Cialis], or sildenafil [Viagra]). The combination of these medications with nitroglycerine can result in life-threatening hypotension. The onset of action is within 1 to 3 minutes, with a maximum effect by 4 to 5 minutes. The major side effect of nitroglycerine is hypotension, but that is short-lived. Administer one pill sublingually and allow 4 to 5 minutes for an effect. The dose may be

repeated a second time. Attempt another technique if the food bolus does not pass after two doses of nitroglycerine.

■ PAPAIN

Papain is a proteolytic enzyme that has been used to dissolve an impacted food bolus. It is available in markets as meat tenderizer and in health food stores as a digestive supplement. It will dissolve the esophageal mucosa and continue to work its way through the esophageal wall and into the mediastinum if it does not first dissolve the food bolus. The use of papain to dissolve an impacted food bolus may be associated with a fatal esophageal perforation and, if aspirated, hemorrhagic pulmonary edema. **Papain should never be used to dissolve an impacted food bolus.**

■ SUMATRIPTAN

Sumatriptan is a 5-HT₁ agonist that reduces fasting fundic tone, prolongs fundic relaxation, and delays gastric emptying.⁴⁴ It increases the number of esophageal motor waves. This may be useful in cases of distal esophageal food boluses and coins, although no formal studies have been conducted.

SHARP AND POINTED FOREIGN BODIES

Removal of sharp and pointed objects requires extreme caution due to potential life-threatening complications, higher morbidity, and higher mortality. **An experienced Endoscopist should manage these cases.** It may be safer in some cases to consider surgical intervention. Toothpicks and bones are the most common foreign bodies requiring surgical removal.⁴⁵⁻⁴⁷ Nails, needles, razor blades, safety pins, and dental prostheses may be removed endoscopically.⁴⁵⁻⁴⁷ It is important to remember that "advancing points puncture while trailing points do not."⁴⁸ Objects longer than 5 cm and wider than 2 cm require removal as they will rarely pass through the pylorus.⁴⁹ Intravenous glucagon in doses of 0.4 to 0.6 mg in adults may be used to facilitate extraction from the stomach and duodenum.

Alligator forceps or snares are needed to grasp the object. Consider the use of a plastic overtube (**Figure 80-2B**) for the removal of any sharp object.^{34,50} The overtube should be at least 60 cm long to remove a sharp object from the stomach. This will limit objects for endoscopic removal to those smaller than 11 to 15 mm in diameter that fit within the overtube.⁵¹ A soft latex protector hood may be used for the removal of large objects.

Razor blade ingestions may be managed with the flexible esophagoscope in adults. An alligator forceps, a snare, and an overtube will be needed. A razor blade that has passed the pylorus will often traverse through the intestinal tract without difficulty.

Safety pins and toothpicks pose additional risks due to their sharp ends that may perforate the esophagus. Push an open safety pin with the open end proximal into the stomach with the flexible endoscope. Turn the safety pin and grasp the hinged end to pull it out (**Figure 80-5**). A closed safety pin in the stomach will often pass without difficulty. Grasp a toothpick with an alligator forceps or snare very close to the tip so that the longitudinal axis of the toothpick is parallel to the scope as it is withdrawn into the overtube.³¹

Numerous other sharp objects are often encountered in the esophagus. Pens, pencils, thermometers, and wires are extracted in a fashion similar to a toothpick with a snare grasping the end of the object.²⁹ Glass may be withdrawn similarly or by using an end-hood attachment.^{50,52}

Attempts should be made to remove all sharp and pointed foreign bodies before they pass from the stomach. Approximately 15% to 35% of sharp or pointed foreign bodies will cause intestinal perforation, especially in the area of the ileocecal valve.^{53,54}

DISK OR BUTTON BATTERIES

Most disk or button batteries ingested (96%) are small and 7.9 to 11.6 mm in diameter.^{55,56} Batteries less than 15 mm in diameter almost never lodge in the esophagus. Only 3% of button batteries are larger than 20 mm, but the batteries are responsible for severe esophageal injuries.⁵⁶⁻⁶¹ Guidelines for the evaluation and treatment of button battery ingestions are available.^{7,62}

Button batteries cause injury by multiple methods.^{57,63-68} Their electrical discharge causes hydrolysis and the creation of hydroxide ions in tissue, which causes alkali burns. Leakage of the high pH contents can result in alkali burns. Their physical presence can cause direct-pressure necrosis. Some button batteries contain mercuric oxide. Mercury toxicity can result if the mercuric oxide leaks from the batteries.

Most of these batteries contain manganese dioxide, silver oxide, mercuric oxide, zinc air, mercuric oxide, or lithium. Obtain anteroposterior and lateral abdominal and chest radiographs to distinguish between coins and button batteries (**Figures 80-1D and 80-7**). A double density shadow is suggestive of batteries. The coin has a much sharper edge. **Do not mistake a battery and a coin.**⁶⁹

A button or disk battery lodged in the esophagus is a true emergency, and immediate removal is indicated to avoid the

rapid corrosive action of the alkaline substance on the mucosa and subsequent complications.^{57,70-73} Endotracheal intubation is usually necessary to protect the airway prior to endoscopic removal. The battery is removed from the esophagus under direct viewing using a through-the-scope balloon. A biopsy forceps may be needed to free the edge of the battery prior to removal. Alternatively, the battery may be pushed to the stomach and then removed using a basket, net, or polypectomy snare. **Do not use a Foley catheter or a magnet to remove a button battery without the aid of endotracheal intubation and general anesthesia due to the possibility of the button battery falling into the airway.**

Admit the patient to the Intensive Care Unit and monitor them for signs of perforation and sepsis if they suffered severe esophageal injury when evaluated by endoscopy after removal of the button battery.⁶⁵ Bronchoscopy may be performed to evaluate the extent of injury if it is localized to the anterior wall of the esophagus.

A button battery in the stomach generally need not be removed unless the patient is symptomatic with abdominal pain, tenderness, or gastrointestinal bleeding. Asymptomatic patients with button batteries less than 15 mm in diameter in their stomachs need follow-up abdominal radiographs every 24 hours to document forward progress until it is expelled. Endoscopically remove the battery if it is larger in size and has not passed within 48 hours in a child less than 6 years old.^{55,74} Patients may be placed on H₂ blockers and/or proton pump inhibitors to decrease the acid in the stomach and decrease the battery reaction. Obtain serum and urine mercury levels and monitor them if mercury poisoning is anticipated.

MAGNETS

Magnets are commonly found in homes and are easily accessible to children. They are contained in appliances, jewelry, and toys. The ingestion of a single magnet is usually not problematic. **The ingestion of multiple magnets is considered an emergency requiring removal.**^{71,75} The magnets can move separately through the gastrointestinal tract. They then have the potential to attract each other and trap bowel between them. This can result in pressure necrosis, fistula formation, and perforation.⁷⁵

Perform plain radiographs to determine the number and the location of the magnets. Treat a single magnet ingestion as any other small, nonsharp, foreign body ingestion. Multiple magnets require removal. Remove them endoscopically if they are located within the esophagus and/or stomach. Consult a Surgeon for urgent removal if they have passed the pylorus versus careful inpatient monitoring by the Surgeon and frequent radiographs to localize the magnets.

NARCOTIC PACKETS

Body packing may be used as a method of an internal concealment of illegal drugs using latex condoms or plastic balloons. Endoscopic removal is contraindicated because any rupture or leakage of the packets will be fatal. Consult a Surgeon for removal in the Operating Room.²⁸

FOLEY CATHETER TECHNIQUE

A Foley catheter has been successfully used to remove recently ingested, radiographically opaque, smooth and blunt foreign bodies from the esophagus.⁷⁶ This technique is inexpensive, has a high success rate, does not require hospitalization, and avoids the complications associated with endotracheal intubation and general anesthesia. Coins are the foreign bodies primarily removed with a Foley catheter. The technique has been used to remove button batteries, food boluses, and other smooth foreign bodies.

FIGURE 80-7. Radiograph of a chest with a foreign body in the esophagus. **A.** Button battery. **B.** Coin. (Photo used with permission from reference 57.)

This technique cannot be used on all patients with an esophageal foreign body. **Do not use this technique in patients who are confused or uncooperative. Endotracheally intubate patients with an altered mental status, airway compromise, or potential airway compromise prior to Foley catheter removal of the foreign body.** Sharp or irregular-shaped objects can lacerate or perforate the esophagus upon removal. Known or suspected esophageal perforation is a contraindication to this technique. Patients with complete esophageal obstruction, as demonstrated by an esophageal air-fluid level on radiographs, are not candidates. Esophageal fibrosis, esophageal tumors, anatomic anomalies, or a history of prior esophageal surgery are also contraindications.

The equipment required for the technique is minimal. This includes topical anesthetic spray, a bite block, and a size 12 to 16 French Foley catheter with a 5 to 10 mL balloon. The technique may be performed ideally in a fluoroscopy suite or blindly in the Emergency Department. A water-soluble contrast agent is required if using fluoroscopy. **The most dangerous and immediate complication**

of this technique is airway obstruction. Airway and emergency equipment must be available if this technique is to be performed.

Explain the procedure to the patient, including the sensations they will experience. The use of a topical anesthetic spray for the oropharynx is beneficial but optional. Its use may increase the risk of aspiration. The use of physical restraints (Chapter 232), procedural sedation (Chapter 159), and/or intubation (Chapter 18) may be required on a case-by-case basis. Preinflate the Foley catheter balloon with 5 to 10 mL of water-soluble contrast material. Inspect the integrity of the balloon. Withdraw the contrast material back into the syringe to deflate the balloon. The small amount of contrast material left in the balloon will facilitate identification under fluoroscopy. Place the patient prone in 10° to 20° of Trendelenburg or in the left lateral decubitus position in 10° to 20° of Trendelenburg. The fluoroscopy technique and then the blind technique are described in the following paragraphs.

Insert the Foley catheter. Some physicians insert a bite block and place the Foley catheter through the mouth (Figure 80-8). Others

FIGURE 80-8. The Foley catheter technique to remove an esophageal foreign body. This illustration demonstrates the oral route for catheter insertion. The nasal route may also be used. **A.** The catheter is inserted and advanced until the balloon is just distal to the foreign body. **B.** The balloon is inflated. **C.** The catheter is withdrawn and pulls the foreign body into the hypopharynx. **D.** Completely withdrawing the catheter will pull the foreign body into and out of the mouth. Steps **C** and **D** are performed in one smooth motion.

use the nasal route. The oral route avoids the potential problem of lodging the foreign body in the nasopharynx with subsequent aspiration. Advance the Foley catheter under fluoroscopy until the balloon is just distal to the foreign body (**Figure 80-8A**). Slowly inflate the balloon with 5 mL of contrast material (**Figure 80-8B**). Stop inflating the balloon if the patient complains of pain. Deflate the balloon and reposition the catheter before reinflating. Withdraw the catheter with moderate and steady traction until it exits the mouth (**Figures 80-8C and 80-8D**). **Stop withdrawing the catheter if resistance is met to prevent an esophageal tear or perforation.** The balloon may occasionally slide past the foreign body as the catheter is being withdrawn. Reinsert the catheter and inflate the balloon with 7 to 8 mL of contrast material and then withdraw the catheter. **Do not overinflate the balloon as it can rupture the esophagus. Do not attempt this technique more than twice.** The balloon will pull the foreign body ahead of it into the hypopharynx and then the mouth. Tell the patient to spit out the foreign body or grasp it (e.g., fingers, forceps, or a hemostat).

This technique may also be used “blindly” if fluoroscopy is not available. Estimate the distance on the radiographs from the mouth or nose to the foreign body. Place the Foley catheter over the radiograph with the balloon just distal to the foreign body. Mark the distance with tape on the catheter as it exits the mouth or nose. Insert the catheter into the patient until the tape is positioned at their mouth or nose. Use saline rather than contrast material to inflate the balloon. Remove the catheter and foreign body as above. Obtain repeat radiographs if the foreign body is not expelled with the catheter as it may have been pushed into the stomach. The remainder of the technique is the same as described for removal under fluoroscopy.

Complications with this technique are uncommon but do occur. This technique may not be able to remove the foreign body. Insertion of the catheter can cause laryngospasm or vomiting. The Foley catheter may enter the airway and result in coughing and laryngospasm. The esophagus may be lacerated or perforated if the foreign body is large, completely impacted, sharp, irregular, or has been in place for over 12 to 24 hours. Overinflation of the balloon can rupture the esophagus. Removal through the nose may result in epistaxis or impaction of the foreign body in the nasopharynx or nasal cavity. The most feared complication is complete or partial airway obstruction if the foreign body falls into the larynx.

BOUGIENAGE

The use of an esophageal bougie to push an esophageal foreign body into the stomach has been used in children.⁷⁷⁻⁸¹ The technique has been successfully used in asymptomatic children who have radiographs documenting a coin in the esophagus and no history of esophageal disease and when less than 24 hours have passed from the time of ingestion. The advantages of this technique are that it is quick, is simple to perform, does not require sedation, does not require intravenous access, decreases length of stay, and saves money when compared to endoscopy.^{77,78,82}

Apply a topical anesthetic spray to the child's oropharynx. Select an appropriate size esophageal bougie. Physically restrain the patient while they are sitting upright or standing on the bed. Place the tip of the esophageal bougie at the mouth and run the rest of it to the earlobe and to just below the left costal margin. Place a piece of tape on the esophageal bougie 3 to 4 cm below the costal margin. Insert the esophageal bougie through the patient's mouth and advance it in one smooth motion until the tape is at the mouth. Remove the esophageal bougie. Obtain a repeat radiograph to confirm that the coin is now in the stomach.

Complications can occur and are avoided with proper patient selection. Esophageal perforation may occur if the patient has

known esophageal disease, prior esophageal surgery or manipulation, a sharp foreign body, or an irregular-shaped foreign body. A foreign body present for more than 24 hours can cause pressure necrosis of the esophagus and increase the risk of perforation.

OROGASTRIC TUBE MAGNET

The orogastric tube magnet (OGTM) is an orogastric tube that has a magnet sealed within the distal end. It may be used to retrieve smooth metallic foreign bodies from the esophagus and stomach under fluoroscopy. Place the patient in the lateral decubitus position. Apply a topical anesthetic spray to the oropharynx. Insert the OGTM through the mouth. Advance the OGTM under fluoroscopy into the esophagus and directed toward the foreign body until it makes contact. Withdraw the OGTM and the foreign body out the mouth. This is a rarely used technique.

LARYNGOSCOPIC REMOVAL

Hypopharyngeal and upper esophageal foreign bodies may be removed with the laryngoscope.⁸³⁻⁸⁵ The Emergency Physician is already familiar with the equipment. The curve of the forceps (e.g., Boedecker, Magill, or Tylke) allows the Emergency Physician to simultaneously view the forceps tip and the hypopharynx. Select the type and size of the forceps based on the availability of different forceps and sizes, the foreign body, and Emergency Physician experience using the forceps. The foreign body must not be embedded. Consider endotracheal intubation before foreign body removal. Have endotracheal intubation supplies and suction readily available.

Use a direct or video laryngoscope. Slowly insert the laryngoscope with the left hand until the epiglottis is observed. Gently insert the forceps and advance it to the foreign body. Open the jaws of the forceps. Move the forceps forward and grasp the foreign body. Gently withdraw the forceps and remove it with the foreign body.

ALTERNATIVE TECHNIQUES

Numerous other methods for the removal of esophageal foreign bodies have been tried and reported in the literature.^{83,86-90} Surgical removal is rarely indicated except when complications (e.g., perforation or vascular penetration) have occurred. **Do not blindly push food boluses into the stomach.** This is hazardous because many patients have underlying esophageal disease. **Blind maneuvers can result in esophageal perforation.**

PEDIATRIC CONSIDERATIONS

Children less than 4 years of age are predisposed to occasionally have an esophageal foreign body. They explore objects with their mouth, have a high curiosity level, lack molars to chew food, and have poor motor and sensory coordination. Common esophageal foreign bodies include balls, button batteries, buttons, candies, coins, gumballs, jacks, marbles, partially chewed food, and pen caps. **A high index of suspicion must be maintained as a history of an ingestion may not be obtained.**^{9-11,58-62}

Children may present asymptotically or with cough, drooling, dysphagia, respiratory distress, unwillingness to eat, or vomiting.⁶⁵ An asymptomatic child with an esophageal coin or round object, except button batteries, can be admitted to the hospital and watched for 24 hours to see if the object will spontaneously pass into the stomach.⁹¹ Remove the object with a esophageal bougie, a Foley catheter, or an endoscope if the child is symptomatic, becomes symptomatic, or if the object does not pass within 24 hours.⁹² Foreign bodies in a mainstem bronchus require removal by an Otolaryngologist in the Operating Room with a rigid bronchoscope.⁹²

Turning the child upside down or performing the Heimlich maneuver may move the foreign body into the trachea or larynx and cause a complete airway obstruction.

Approximately 25% to 30% of esophageal coins in children pass spontaneously without complications.⁸⁶ Treatment of these patients may reasonably include a period of observation of 8 to 16 hours, especially in older children with coins in the distal esophagus. A “combination” technique using fluoroscopy and endoscopic forceps, called the “penny-pincher,” has been described to remove coins in children.⁸⁷ In this technique, grasping endoscopic forceps are covered by a soft rubber catheter and fluoroscopically guided into place. The forceps firmly hold the coin while the catheter protects the oropharynx and aligns the device with the coin. When the tip of the catheter is close to the upper edge of the coin, the retracted radiopaque prongs of the forceps are deployed. The coin edge is grasped and the coin is extracted.

It is important not to attempt these techniques or bougienage with patients with known anomalies of the gastrointestinal tract.⁹² These anomalies may be anatomic, functional, or postsurgical. They can lead to the coin again becoming lodged, this time in a position that would require a more invasive intervention than endoscopy.⁸⁸

ASSESSMENT

Observe the patient until the effects of the sedation, if used, have resolved per hospital policy. Give the patient a trial of liquids to swallow (i.e., drink) prior to discharge. The patient may be safely discharged after they tolerate oral fluids, are awake and oriented, and ambulate without difficulty. The patient should be driven home by another person if sedation was used to extract the foreign body.

Admission is required in a few instances. The inability to tolerate oral fluids is a contraindication to discharge. Admit patients with foreign bodies that are not retrievable in the Emergency Department for observation, further endoscopy, or operative removal. Any patient with evidence of esophageal perforation should be admitted, observed, and evaluated by a Surgeon.

Examine the esophagus endoscopically after removal of most foreign bodies. Consult a Gastroenterologist on anyone with an esophageal foreign body. Note the presence of any lacerations, perforations, or erosions that may require repair. Any strictures will require dilation in the future.

AFTERCARE

Instruct the patient to only ingest liquids for the first 12 to 18 hours. Begin a soft diet after this trial period of liquids and advanced to a general diet over 24 hours. Instruct the patient to take small bites of food and completely chew it before swallowing. They should immediately return to the Emergency Department if they experience abdominal pain, chest pain, dysphagia, hematemesis, hemoptysis, melena, or odynophagia, or if they have any concerns. All patients discharged from the Emergency Department should follow-up with a Gastroenterologist in 24 to 48 hours.^{72,93} Some recommend a second endoscopic follow-up in 3 to 6 weeks for reevaluation of the esophagus. This is up to the consultant.

COMPLICATIONS

Esophageal perforation can occur due to the foreign body or the extraction procedure.^{17,94-96} The patient may present with fever, tachycardia, shortness of breath, chest pain, abdominal pain, and crepitation in the neck. Perform an immediate chest radiograph and/or a radiographic contrast study if the extraction of the foreign body has been difficult.^{1,2,4} An aorto-esophageal fistula can form due to sharp foreign bodies in the esophagus that erode through the esophageal

wall. This should be considered when the patient presents with dysphagia and significant hematemesis.^{22,50} A latency period between the ingestion of the foreign body and hematemesis is usually 1 to 3 weeks, although it can occur years later.²⁹ Tracheoesophageal fistulas can occur more than a year after ingestion of the foreign body.⁴

Other life-threatening cardiopulmonary emergencies include mediastinitis, lung abscess, pericarditis, cardiac tamponade, pneumothorax, and pneumomediastinum. These complications mostly result from a delay in recognizing an esophageal perforation.^{21,22,29} The remaining complications are discussed with each of the individual techniques of foreign body removal.

SUMMARY

Foreign body ingestion and food bolus impaction in the upper gastrointestinal tract are relatively common problems seen in the Emergency Department. Several studies have shown that 80% to 90% of foreign bodies in the gastrointestinal tract will pass spontaneously. Approximately 10% to 20% will require nonoperative intervention, while 1% will require surgical removal.^{4,88} The most common presenting symptoms are chest or pharyngeal pain, odynophagia, dysphagia, foreign body sensation, and sialorrhea.⁸⁹ No foreign body could be found in almost half of patients despite performing emergent upper endoscopy.⁹⁰ The urgency for the endoscopic examination depends on the potential risk of aspiration or perforation, the type and size of the foreign body, the degree of obstruction, and the inability to manage secretions.²² The presence of dysphagia and the immediate onset of symptoms would increase the probability of a positive foreign body finding on endoscopy.

Numerous techniques may be used to remove an esophageal foreign body. The technique of choice depends on the level of patient cooperation, the type of foreign body, the time since ingestion, physician experience and comfort, Gastroenterology consultation, and presenting symptoms. Complications can be minimized by the proper selection of the removal technique and the appropriate patient for the technique.

Balloon Tamponade of Gastrointestinal Bleeding

Bashar M. Attar

INTRODUCTION

Gastroesophageal varices are among the most dangerous complications associated with cirrhosis. They are present in 50% to 60% of cirrhotic patients.¹ Approximately 30% of patients will experience an episode of variceal hemorrhage within 2 years of the diagnosis of varices.¹ The major factors that determine the risk of bleeding are variceal size and the degree of liver dysfunction.¹⁻³ Variceal bleeding stops spontaneously in 20% to 30% of cases.¹⁻⁴ It recurs in 70% of patients within 1 year of the initial episode.¹⁻⁴ Mortality is as high as 50% in the first year.⁵ Variceal bleeding accounts for almost one-third of deaths in cirrhotic patients. Variceal hemorrhage has a poor

prognosis if it is associated with coexisting or subsequent complications (e.g., rebleeding, infection, hepatic dysfunction, and portal pressure ≥ 12 mmHg).^{6,7} Somatostatin and its analogues cause splanchnic vasoconstriction, leading to reduced portal pressure and portal blood flow, whereas venodilators reduce portal pressure by reducing resistance to portal flow.^{7,8}

Doctors Sengstaken and Blakemore developed the concept of balloon tamponade to control bleeding esophageal and gastric varices in 1950. They developed a triple-lumen and double-balloon system that bears their names. **The Sengstaken-Blakemore (SB) tube is used as a temporizing measure to stop variceal bleeding until more definitive means are available (Figures 81-1 and 81-2).** The SB tube was designed for the control of esophageal varices and as a diagnostic aid to determine the source of hemorrhage into the stomach. There are variants of the SB tube (e.g., the Minnesota tube and the Linton-Nachlas tube). The Minnesota tube is a quadruple-lumen, double-balloon system (**Figure 81-3**).⁹ The Linton-Nachlas tube was designed with only an esophageal balloon (**Figure 81-4**). It controls bleeding for esophageal varices. These tubes are rarely used today due to the significant complications and the widespread availability of endoscopy and its therapeutic interventions.

Removal of the balloon after its initial control of the bleeding results in a 50% rebleeding rate. The tubes are associated with serious complications (e.g., esophageal ulceration and perforation).¹⁰ Emergency Physicians should become familiar with the SB and Minnesota tubes. They can be potentially lifesaving in an emergent setting to achieve bleeding control when endoscopy is contraindicated, fails, or is not immediately available.¹¹⁻¹³

ANATOMY AND PATHOPHYSIOLOGY

The venous anatomy of the abdominal cavity and thorax is shown in **Figure 81-5**. The veins of the torso are devoid of valves. There are extensive connections (i.e., anastomoses) between the veins. This extensive network of veins allows blood multiple ways to return to the heart. Many of the veins are small. They can enlarge to accommodate the extra flow of blood.

Cirrhosis results in portal venous hypertension and a decrease in blood flow through the portal system. Collateral circulation develops so that the blood in the portal vein can find an alternative route to the inferior vena cava. Large collateral systems include the esophageal, gastric, paraumbilical, and rectal veins. The left gastric and esophageal veins form one of the larger collateral circulation channels due to the pressure generated from the portal venous system and the large volume of blood flow through them.

The collateral veins distend from the pressure and large volume of blood flow, which results in weakening of the walls of the vein. Ulceration and rupture of these veins can result in large amounts of blood entering the esophagus and stomach. Patients may present with bright red blood per rectum, hematemesis, hemorrhagic shock, hypotension, or complications associated with hypotension and hemorrhage (e.g., cerebrovascular accidents and myocardial infarction).

The inflated balloons will control most bleeding. The esophageal balloon exerts lateral pressure to tamponade esophageal varices. The gastric balloon exerts pressure on the gastric cardia to tamponade varices. Both balloons are inflated and meet to compress the gastric cardia against the diaphragm and block the upward flow of collateral blood from feeding the esophageal varices.

INDICATIONS

Consider balloon tamponade in patients with acute bleeding from esophageal and/or gastric varices if medical therapy (e.g., somatostatin, octreotide, vasopressin) or emergent endoscopic therapy

FIGURE 81-1. Schematic illustration of the Sengstaken-Blakemore tube.

(i.e., banding or sclerotherapy) is not available, contraindicated, or unsuccessful.

CONTRAINDICATIONS

Absolute contraindications to balloon tamponade of variceal bleeding include a history of esophageal stricture, a history of recent surgery involving the gastroesophageal junction, or if the hemorrhage has terminated based on nasogastric lavage and aspiration.

There are numerous relative contraindications to balloon tamponade of variceal bleeding. Do not perform the procedure if the equipment required is defective or missing components. Untrained support staff make the procedure and aftercare more difficult. Significant active medical problems (e.g., respiratory failure, congestive

heart failure, and cardiac arrhythmias) preclude the use of balloon devices. Incomplete gastric lavage leaving particulates in the stomach can cause retching and elevated intraabdominal pressure. The balloons will not properly position and may perforate the esophagus if the patient has a hiatal hernia. Esophageal ulcerations preclude the use of the esophageal balloon, but the gastric balloon may be used. The device is not helpful if a variceal source of bleeding cannot be demonstrated by examination, history, and/or nasogastric aspiration.

Secure the airway of patients with altered mental status, confusion, diminished gag reflexes, or hypoxemia or who are uncooperative by endotracheal intubation prior to this procedure. Recurrent bleeding after the initial successful tamponade should be followed by endoscopic or operative intervention.

EQUIPMENT

- SB tube or Minnesota tube
- Topical anesthetic spray
- Tongue blades
- Lidocaine or water-soluble jelly
- 60 mL syringe
- Catheter tips for the syringe
- Two wall-suction setups with plastic connectors and suction tubing
- Adhesive tape
- Rubber shod clamps, hemostats, or plugs
- Scissors

- Y-adapter or three-way stopcock
- Intravenous extension tubing
- Pressure bulb
- Mercury manometer or handheld manometer
- Bite block
- Nasogastric tube
- Football helmet, catcher's mask, or endotracheal tube holder

FIGURE 81-4. The Linton-Nichlas tube.

The SB tube is a triple-lumen and double-balloon system (**Figures 81-1 and 81-2**). It is available in a variety of sizes, including pediatric sizes. The proximal end contains three ports. A syringe attaches to the esophageal balloon inflation port to inflate the esophageal balloon. A syringe attaches to the gastric balloon inflation port to inflate the gastric balloon. The gastric aspiration port may be used to aspirate gastric contents, instill fluid into the stomach, or lavage the stomach. The ports may be opened and closed by the application of rubber shod clamps, hemostats, or plugs. The tube is made of a soft rubber and is extremely flexible. The proximal or esophageal balloon is elongated. The distal or gastric balloon is round. The maximum volume to inflate each balloon is specific to the manufacturer. Numerous perforations in the distal end of the tube allow for gastric aspiration and lavage.

The Minnesota tube is a quadruple-lumen and double-balloon system (**Figure 81-3**). It is similar to the SB tube with the exception of an additional port and lumen. The esophageal aspiration port allows saliva and esophageal secretions to be aspirated from a perforation just above the esophageal balloon. The only advantage of this tube over the SB tube is that the SB tube requires a nasogastric tube to be passed nasally or orally into the esophagus to aspirate secretions.

The Linton-Nachlas tube is a triple-lumen and single-balloon system (**Figure 81-4**). It is similar to the SB tube with the exception of one balloon. The esophageal aspiration port allows saliva and esophageal secretions to be aspirated from a perforation just above the esophageal balloon. The gastric aspiration port allows gastric secretions to be aspirated from below the balloon.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure, and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent

the option to leave the room or look away as the procedure can be disconcerting to some parents.

Thoroughly assess the patient's airway and breathing. **Have a low threshold to protect the airway by endotracheal intubation (Chapter 18).** Endotracheal intubation is required before performing the procedure if the patient has altered mental status, airway compromise, or the potential for airway compromise. Patients are often ill and require intubation for other reasons.¹⁴ The procedure and the tube are not well tolerated, and intubation makes it easier. Endotracheal intubation reduces the risk of aspiration.

Establish intravenous access with at least two large-bore catheters. Apply cardiac monitoring, continuous pulse oximetry, and supplemental oxygen. The patient may require the judicious use

A

FIGURE 81-5. The veins of the torso. (Photos used with permission from Duty B, Daneshmand S: Venous resection in urological surgery. *J Urol* 2008; 180(6):2338-2342.)

FIGURE 81-5. (continued)

of intravenous sedatives (Chapter 159) and soft restraints (Chapter 232) during the insertion and inflation of the tube. Resuscitate the patient to stabilize them hemodynamically.

What is the ideal position? Place the patient sitting upright to semi-upright by elevating the head of the bed at least 45°. The procedure can be performed with the patient in the left lateral decubitus position if they cannot sit upright. The procedure can be performed with the patient supine if they are endotracheally intubated.

Apply topical anesthetic spray to the nostrils and pharynx. Insert a nasogastric tube (Chapter 75) or Ewald tube (Chapter 77). Aspirate the stomach contents. Evacuate the stomach with tap-water lavage through the nasogastric tube or Ewald tube. Remove the nasogastric or Ewald tube.

Prepare the equipment. Flush the aspiration ports with air to ensure their patency. Inflate the balloons with the maximum recommended volume of air and check for leaks. It is advisable to inflate the balloons under water to look for small leaks. Connect the mercury manometer to the balloon ports and inflate the balloons to the recommended pressures and check for leaks. Completely deflate the balloons. Record the manometric pressure of each balloon when it is deflated. Insert the plastic plugs in the balloon inflation ports or loosely clamp each port with a hemostat or rubber shod clamp.¹⁵⁻¹⁷ Lubricate the SB tube with a water-soluble lubricant. Place the SB tube on a table. Position a nasogastric tube next to the SB tube so that the tip of the nasogastric tube is just above the esophageal balloon (Figure 81-6). Place a piece of tape on both tubes to mark a common point, proximal to the 50 cm mark of the SB tube, that will be outside of the patient. The nasogastric tube will be inserted after

the SB tube is placed. Alternatively, position the tubes as above and tape both tubes together at two or three sites. This allows the nasogastric tube to be inserted simultaneously with the SB tube.

The SB tube may be inserted through the nose or through the mouth. The nasal route is more difficult to use and may be associated with a higher rate of complications. Many physicians recommend the nasal route in the awake patient. The oral route is the preferred route of insertion by some if the patient is intubated. Apply topical anesthetic spray into the nasal cavity and oropharynx if the SB tube will be placed nasogastrically. Apply topical anesthetic spray into the oropharynx if the SB tube will be placed orally. Place a bite block in the patient's mouth if the SB tube will be placed orally to prevent the patient from biting the SB tube.

TECHNIQUES

SB TUBE

Insert the lubricated SB tube until the 50 cm mark is located just outside the nares, or outside the teeth if inserted through the mouth. Flush the gastric aspiration port with air while auscultating over the epigastrium (Figure 81-7A). A rush of air should be heard to ensure that the distal end of the SB tube is properly positioned within the stomach. If possible, confirm the position of the SB tube with portable plain radiographs or fluoroscopy (Figure 81-7B).¹⁴ **It is imperative to know that the gastric balloon is within the stomach before it is inflated.**¹⁸ Apply suction to the gastric aspiration port.

FIGURE 81-6. Preparing the nasogastric tube. Place the nasogastric tube alongside of the SB tube with the tip just above the esophageal balloon. Place tape on both tubes to mark a common point proximal to the 50 cm mark on the SB tube.

Remove the rubber shod clamp and plastic plug from the gastric balloon inflation port. Connect the Y-adapter with a handheld or mercury manometer and a pressure bulb or a 50 mL syringe with a catheter tip to the gastric balloon inflation port (**Figure 81-8**). Measure the uninflated intragastric balloon's pressure. **If the intragastric balloon pressure after intubation is 15 mmHg greater than that prior to the intubation, deflate the balloon as it may be located within the esophagus.** Inflate the gastric balloon in increments with 50 to 100 mL boluses of air (**Figure 81-9**). **Deflate the balloon immediately if the patient experiences chest pain. This signifies that the gastric balloon is in the esophagus.** Clamp the gastric balloon inflation port when the gastric balloon is inflated initially with 200 to 250 mL of air. Pull the SB tube back gently until resistance is felt as the gastric balloon lodges against the gastroesophageal junction (**Figure 81-10**).

Apply slight tension to the SB tube to occlude the veins at the gastroesophageal junction. **This tension must be maintained by one of several methods.** Fix the upper end of the SB tube as it exits from the mouth or nose to the crossbar of a football helmet or a catcher's mask (**Figure 81-11**). Apply over-the-bed traction with a 1 pound weight (**Figure 81-12**). Fix the upper end of the SB tube, if it emerges from the nostril, by a cuff of sponge rubber held in place by an adhesive tape band. The tube can be secured to a cervical collar (**Figure 81-13**).¹⁹ Insert the nasogastric tube until the tape is at the level of the tape on the SB tube (**Figure 81-14**).

Connect the gastric aspiration port and the nasogastric tube to the suction source (**Figure 81-15**). Place the gastric aspiration port and the nasogastric tube on low intermittent suction. Unclamp the esophageal balloon port clamp. Attach the Y tubing, manometer,

A

B

FIGURE 81-7. The SB tube has been inserted until the 50 cm mark is just outside the teeth. **A.** Inject 50 mL of air while auscultating over the epigastric area. A rush of air should be heard if the distal end of the SB tube is within the stomach. **B.** Chest radiograph of the subdiaphragmatic placement of the gastric balloon. (Photo used with permission from reference 14.)

and pressure bulb (or 50 mL syringe) to the esophageal balloon port (**Figure 81-15**). Inflate the esophageal balloon to a pressure of 25 mmHg if bleeding continues through the gastric aspiration port or the nasogastric tube. If bleeding continues to persist, increase the

esophageal balloon pressure in 5 mmHg increments until 45 mmHg is achieved or the bleeding stops. Double clamp the SB tube to prevent accidental deflation of the balloons. The continued bleeding despite maintaining the esophageal balloon pressure at 45 mmHg

FIGURE 81-9. The gastric balloon is inflated with 50 to 100 mL increments of air to a volume of 250 to 300 mL.

FIGURE 81-10. Tension is applied to the SB tube to lodge the gastric balloon against the gastroesophageal junction.

FIGURE 81-11. The SB tube is commonly secured to the faceguard of a football helmet (A) or to a catcher's mask (B).

is suggestive of a gastric wall varix. Check that the tube is snugged up firmly and taped securely. Fill the gastric balloon with more air gradually up to a total volume of 300 mL of air.

MINNESOTA TUBE

The above technique is also applicable to the four-lumen esophago-gastric tamponade Minnesota tube. This tube is a modification of the triple-lumen SB tube that incorporates a separate esophageal suction port to the existing gastric suction port.^{20,21} The design of the Minnesota tube may help prevent aspiration of esophageal contents.²² Always check the manufacturer characteristics regarding the maximum inflation volume of both the gastric and esophageal balloons, as these are dependent upon the tube manufacturers.

LINTON-NACHLAS TUBE

The insertion of the Linton-Nachlas tube is similar to the SB tube. The only difference is that it only has the esophageal balloon and inflation port. It does not have a gastric balloon or gastric inflation

port. It only stops esophageal bleeding. This tube is rarely stocked in the Emergency Department.

ALTERNATIVE TECHNIQUE

An effective method for placement of the SB tube is endoscopically.^{23,24} This method will avoid the need to obtain radiologic confirmation of the gastric balloon within the stomach.²³ Delay in treatment while waiting for a radiologic confirmation may put patients at risk, as they are almost always in critical condition and require immediate attention.⁴⁻⁶ If endoscopic intervention is not successful, pass an SB tube and confirm the position of the gastric balloon under direct

FIGURE 81-12. A pulley-traction device.

FIGURE 81-13. The tube is secured to a cervical collar. (Photo used with permission from reference 19.)

FIGURE 81-14. The nasogastric tube is inserted until the tape mark lines up with the tape mark on the SB tube. The football helmet/catcher's mask is omitted from this illustration for the sake of clarity.

visualization through the endoscope. The balloons are inflated and secured in the usual fashion.²³

ASSESSMENT

Check the pressure in the balloons periodically with the mercury manometer or keep the manometer attached for constant monitoring. Obtain a portable radiograph to confirm proper placement of the SB tube and the inflated balloons. The patient may be reclined, but always maintain at least 6 to 10 inches of head elevation on the

FIGURE 81-15. The esophageal balloon is inflated after the gastric aspiration port and the nasogastric (NG) tube have been attached to a suction source. The football helmet/catcher's mask is omitted from this illustration for the sake of clarity.

FIGURE 81-16. Emergent removal of the SB tube. Cut the SB tube between the ports and the patient to deflate both balloons rapidly.

bed to prevent aspiration in the awake patient. Tape a scissors to the head of the bed for quick access in case the balloon requires emergent deflation (**Figure 81-16**).

AFTERCARE

If the bleeding is controlled, reduce the esophageal balloon pressure by 5 mmHg every 3 hours until 25 mmHg is reached without bleeding from the nasogastric tube in the esophagus or the gastric aspiration port. Deflate the esophageal balloon for 5 minutes every 6 hours to avoid esophageal pressure necrosis. Give the patient nothing by mouth. Oral medications, if required, may be administered through the gastric aspiration port. Check the tension on the SB tube every 3 hours and adjust it as necessary. Verify patency of the SB and nasogastric tubes by checking the gastric and esophageal return regularly and periodically flushing both lumens.

Monitor the patient continuously for signs of chest pain, respiratory distress, and aspiration. **Migration of the esophageal balloon into the hypopharynx of an awake patient will result in respiratory distress. This situation is a true emergency, and the tube should be removed immediately.** Cut the SB tube between the ports and the patient with a scissors (**Figure 81-16**). The balloons will immediately deflate and allow the removal of the SB tube.

The esophageal balloon should not remain inflated for more than 24 hours to avoid mucosal necrosis. The SB tube is usually left in place with the gastric or gastric and esophageal balloons inflated for 24 hours if variceal bleeding is controlled. If there is no bleeding after 24 hours, deflate the esophageal balloon and leave the gastric balloon inflated for an additional 24 hours. The SB tube may be left in place for an additional 24 hours after both balloons are deflated. If variceal hemorrhage recurs, reinflate the appropriate balloons while alternative therapy to control bleeding is sought. Patients who rebleed have a higher mortality rate. Consider other therapeutic interventions (e.g., rubber banding, sclerotherapy, transjugular intrahepatic portocaval shunt, or surgery). Remove the SB

tube if hemostasis persists for 24 hours after deflation of both balloons. Control of esophageal variceal bleeding can be achieved by balloon tamponade in 50% to 94% of patients.²⁵⁻²⁹ Rebleeding occurs in 38% of patients.

COMPLICATIONS

Major complications occur in up to 15% of patients.²⁵⁻²⁹ Lethal complications have been described in up to 6.5% of patients.²⁵⁻²⁹ **Complications associated with the SB tube are often life-threatening.** The airway may become occluded due to proximal migration of the esophageal balloon into the hypopharynx of the awake patient from traction on the SB tube.³⁰ The patient will begin choking and gagging if not intubated. **Cut the SB tube distal to the ports to immediately deflate the balloons and allow the SB tube to be removed.** Pulmonary aspiration and subsequent pneumonia may occur during SB tube insertion. Consider airway protection by endotracheal intubation in all patients prior to insertion of the SB tube.²⁵

The SB tube may still become malpositioned and end up in the airway despite endotracheal intubation.^{18,31} Inflation of the balloons in the airway can result in respiratory distress, respiratory tract obstruction, tracheal or bronchial rupture, or tracheoesophageal fistulas from pressure necrosis. **It is essential to confirm proper placement prior to inflating the balloons.** A video laryngoscope can be used to place the tube into the esophagus and not the trachea.³²

Excessive balloon pressure or prolonged balloon inflation may lead to pressure necrosis and ulcerations of the esophagus, gastroesophageal junction, and/or stomach. Periodic deflation of the esophageal balloon every 6 hours will help prevent this. Rupture or lacerations of the esophagus, stomach, or small intestine may occur.²⁶ Esophageal rupture can result in mediastinitis, abscess formation, and sepsis. These can be prevented by adhering to proper balloon inflation techniques with pressure monitoring. Cardiac arrhythmias and pulmonary edema can occur and require continuous monitoring in the setting of an Intensive Care Unit. Distension of the stomach can cause inferolateral ST-segment elevation on the electrocardiogram.³³ The balloon can cause extracardiac compression of the heart.³⁴ Pulmonary edema is often due to pressure from the esophageal balloon on mediastinal structures.

Numerous other complications are associated with the use of the SB or Minnesota tube. Inflation of the gastric balloon in the esophagus can cause a ruptured esophagus (**Figure 81-17**).³⁵⁻³⁷ The tube can break above the balloons and require endoscopy to retrieve the balloons.³⁸ Unintentional deflation of the balloons can be prevented by the application of rubber shod clamps or hemostats to the balloon inflation ports after the balloons are inflated. Cut the SB tube distal to the ports if the balloons will not deflate. The patient may become agitated from the discomfort of the tube, migration of the tube into the hypopharynx resulting in hypoxemia and asphyxiation, or as chest and back pain is experienced from a misplaced or overdistended balloon. Hiccoughs are due to pressure on the diaphragm by the balloons. Excessive traction on the tube can result in epistaxis or pressure necrosis of the lips, nose, or tongue.³⁹ The helmet can cause pressure necrosis of the face.⁴⁰ Use air and not a liquid to inflate the balloons. Liquid in the balloons causes them to be heavy, increases the risk of pressure necrosis, and makes them hard to deflate.

SUMMARY

Balloon tamponade of variceal bleeding is an uncommonly performed procedure in the Emergency Department. The SB tube plays an important role in the temporary control of hemorrhage from esophageal or gastric varices.²⁷⁻²⁹ It is used in cases of variceal bleeding, usually documented by endoscopy, that continues

A

B

FIGURE 81-17. The inflation of the gastric balloon (arrows) in the esophagus. **A.** Chest radiograph. (Photo used with permission from reference 37.) **B.** Autopsy photo of an esophageal rupture between the arrows. (Photo used with permission from reference 35.)

despite aggressive medical management (e.g., lavage, correction of blood clotting abnormalities, intravenous somatostatin or vasopressin infusion, rubber banding, and emergent sclerotherapy).^{23,41-43} The SB tube can be placed if these methods are contraindicated or unavailable. Sustained bleeding control occurs in only 40% to 50% of patients.⁴⁴ Balloon tamponade has been shown to be as effective as intravenous vasopressin in controlling esophageal variceal bleeding. Only 25% of patients with ascites, jaundice, and encephalopathy achieve lasting hemostasis with balloon tamponade. Long-term efficacy in terms of rebleeding depends in part on the patient's

underlying liver disease.²³ Maintain a low threshold to intubate the patient endotracheally to prevent aspiration, protect the airway, and prevent airway occlusion from migration of the esophageal balloon.

Gastrostomy Tube Complications and Replacement

Erika Flores Uribe and Erick Eiting

INTRODUCTION

The gastrostomy tube (G-tube) is a commonly used device that provides prolonged enteral support in patients who are unable to obtain sufficient nutrition orally. Indications for enteral feeding tube placement include prolonged neurogenic or mechanical dysphagia, prolonged mechanical ventilation, and poor intake. Relatively common complications related to enterostomy tubes encountered in the Emergency Department include tube dislodgement, tube occlusion, leakage around the tube, and skin changes (e.g., hypergranulation, ulceration, erythema, and infection).^{1,2} Some less common problems include buried bumper syndrome, peritonitis, gastric outlet obstruction, gastro-colo-cutaneous fistula, and stomal herniation.¹⁻⁵ Some of the complications may require replacing G-tubes.⁶ Simplified techniques for their placement and improved materials have made gastrostomies common in the outpatient setting. Emergency Physicians fill a valuable role in solving G-tube problems as many

patients present to Emergency Departments with various G-tube complaints. This chapter reviews the methods and materials used in gastrostomies and the approaches to replacing displaced or malfunctioning G-tubes.

ANATOMY AND PATHOPHYSIOLOGY

Familiarity with the basic techniques used to create gastrostomies and the characteristics of common G-tubes is helpful in solving problems with their function and replacement.

PLACEMENT OF G-TUBES

The choice of access route (i.e., gastrostomy, gastrojejunostomy, or jejunostomy) and the choice of placement technique (i.e., surgical, endoscopic, or radiologic) often depend on individual patient issues and the treating physician (e.g., specialty, experience, and preference). Feeding tubes have been surgically placed in patients for more than a century. Three main procedures that remain in use today are the Stamm (described in 1894), the Witzel (described in 1891), and the Dupage and Janeway (described in 1913) (**Figure 82-1**).⁷⁻¹² They all require a laparotomy under general anesthesia and provide long-term access to the stomach for feedings or decompression while attempting to minimize the potential for gastric leakage.

Each of the techniques attempts to create a leakproof interface between the stomach, the feeding tube, and the anterior abdominal wall. The Stamm gastrostomy secures the stomach to a G-tube using a double purse-string suture to invaginate the stomach about the feeding tube (**Figure 82-1A**). The Witzel technique places the G-tube through a seromuscular tunnel in the stomach wall (**Figure 82-1B**). The Janeway technique creates a formal tunnel from a gastric flap to envelop the G-tube and form a gastrocutaneous stoma (**Figure 82-1C**). **All three techniques involve suturing the stomach wall to the under-surface of the abdominal wall.** The stomach wall remains attached to the abdominal wall, and chance of intraperitoneal contamination is decreased if a surgically placed G-tube is accidentally dislodged in the early postoperative period. These surgical gastrostomies are considered long-term or semipermanent stomas.

Modern endoscopic techniques have provided a less invasive option for the placement of percutaneous feeding tubes (i.e., G-tubes, percutaneous endoscopic gastrostomies, or PEGs).¹³ Distinct advantages of endoscopically placed G-tubes over surgically placed tubes include relative ease of placement, avoidance of general anesthesia, smaller incisions, and a lower morbidity rate.^{8,13,14} The disadvantages of endoscopic techniques include the inability to place tubes in patients with thick abdominal walls, a history of multiple previous operations, the presence of abdominal wall hernias, and an increased risk of injuring overlying viscera during the “blind” placement of the PEG tube. Another disadvantage is the

unique danger of accidental dislodgement of a newly placed PEG tube. If a new PEG tube is dislodged, the stomach wall gastrotomy can pull away from the abdominal wall, allowing the escape of gastric secretions and feedings with resultant peritonitis.

Popular endoscopic techniques in use today require two persons—an Endoscopist and an operator at skin level. An endoscope is first advanced into the stomach (**Figure 82-2A**). The stomach is then insufflated with air to displace adjacent or overlying loops of bowel and appose the stomach wall to the anterior abdominal wall (**Figure 82-2B**). The Endoscopist then visualizes the light of the endoscope as it transilluminates the abdominal wall. They then pierce the anterior abdominal wall with a hollow-bore needle. (**Figure 82-2C**). The Endoscopist confirms placement into the gastric lumen (**Figure 82-2C**).

The G-tube is then placed. A guidewire is fed into the stomach through the needle, grasped with an endoscopic snare, and pulled out of the patient's mouth (**Figure 82-2C**). The “Ponsky pull” technique uses this guidewire as a means for pulling the G-tube into position through the patient's mouth (**Figure 82-3A**). The guidewire is secured around a G-tube and pulled retrograde from the mouth to the exit site on the anterior abdominal wall. The “Ponsky push” technique involves pushing the G-tube down and over the guidewire toward the gastrostomy site (**Figure 82-3B**).¹⁵ The “Russell poke” eliminates the need to direct the G-tube through the mouth.¹⁶ A dilator is used under direct visualization to enlarge the skin puncture site. An introducer and peel-away sheath are then used to place the G-tube directly through the anterior abdominal wall (**Figure 82-3C**). **Regardless of which technique is used to establish the gastrostomy, the stomach is not sutured to the abdominal wall.** A fibrous tract eventually forms between the anterior abdominal wall and the stomach. **The maturation of this tract is an important consideration in assessing G-tubes.**

Endoscopy-guided percutaneous gastrostomy (PEG) tubes are commonly placed in patients in whom oral intake is contraindicated.¹⁷ A PEG tube may not be preferred in mechanically ventilated or critically ill patients due to risk of aspiration. Administration of the nutrients directly into the jejunum through a percutaneously placed jejunostomy tube is recommended to bypass the stomach and decrease the risk for aspiration.¹⁸ Other indications for direct administration of nutrients into the jejunum include malfunction of the swallowing mechanism, gastric outlet obstruction, gastroparesis, pancreatitis, and the presence of esophageal fistulas or enteric foregut leaks.¹⁸ A meta-analysis found that radiologically guided gastrostomy compared favorably with surgical and endoscopic gastrostomy, with similar or improved success and complication rates.¹⁹

Radiologic percutaneous gastric fixation is only required for tubes that are pushed through the abdominal wall (i.e., percutaneous radiologic G-tubes or percutaneous radiological gastrojejunostomy

FIGURE 82-1. Surgical gastrostomies. **A.** The Stamm technique. **B.** The Witzel technique. **C.** The Janeway technique.

FIGURE 82-2. Endoscopic G-tube placement. **A.** The endoscope is inserted. **B.** The stomach is inflated with air and transilluminated. **C.** The anterior abdominal wall is pierced with a cannula or needle under endoscopic guidance. A suture or guidewire is then introduced into the gastric lumen and grasped with a snare.

[GJ] tubes). There are two kinds of anchor devices made of short metal bars attached to a surgical suture: the Cope suture anchor (Cook, Bloomington, IN) and the T-fastener (Boston Scientific, Natick, MA). Anchors are inserted into the stomach using a gastropexy set. Multiple anchors are required for 12 French or larger tubes. Tract dilatation with fascial dilators exerts a large amount of force. The performance of gastropexy is controversial but standard.

TYPES OF G-TUBES

There are many types of G-tubes available. A basic understanding of G-tubes is all that is needed to diagnose and treat most problems. Familiarity with the characteristics of G-tubes is helpful in assessing tube function and determining appropriate replacements.

Not all G-tubes can be removed safely in the Emergency Department. Standard de Pezzer and mushroom catheters modified with rings or bolsters may require endoscopy for removal. GJ-tubes will need advanced replacement techniques to appropriately place the jejunal part of the tube. Contact the provider who inserted the tube to determine if removal can be completed safely in the Emergency Department when in doubt. **The visible portion of the G-tube outside the skin may or may not indicate what type of internal stabilization exists.**

The G-tube is simply a conduit for enteral feedings. The essential features of the G-tube include the tube, an internal bolster, an external fixation (i.e., bolster or retention) device, and the ports (**Figure 82-4**). The main body of the G-tube is made of silicone or polyurethane. It is designed to minimize tissue reactions and optimize patient comfort. G-tubes come in a variety of sizes ranging from 12 to 24 French. Some are reinforced with an inner steel wire. Many come with external identification marks to denote caliber, commercial brand name, centimeter markings to aid in positioning, and radiopaque lines to aid in radiographic identification (**Figure 82-4**).

The internal bolster fixes the G-tube within the lumen of the stomach and creates a seal to discourage leaking (**Figure 82-4**). Commercially available PEG tubes come with a variety of choices for internal bolsters including balloons, crossbars, T-bars, flanges, round disks, three-leaf retainers, soft domes, and others (**Figure 82-5**). The most basic tubes use a balloon as an internal bolster. Surgical gastrotomies commonly use Foley balloon catheters, mushroom-tip de Pezzer catheters, or Malecot catheters. Some internal bolsters are deformable and allow removal with gentle traction on the external tube. Others are not intended to give way with traction and require more invasive techniques for removal. **The nature of the internal bolster will determine if a G-tube can be removed in the Emergency Department or requires endoscopic removal.**

FIGURE 82-3. Endoscopic G-tube placement. **A.** The "Ponsky pull." A suture is attached to a modified G-tube and pulled in a retrograde direction through the anterior abdominal wall. **B.** The "Ponsky push." A guidewire serves as a trolley for the G-tube to be pushed over. **C.** The "Russell poke." The G-tube is inserted through a peel-away sheath.

FIGURE 82-5. Examples of internal bolsters used in PEGs. **A.** Mushroom tip with de Pezzer flange. **B.** Crossbar. **C.** Round disk. **D.** Balloon tip. **E.** Malecot. **F.** Soft dome.

External bolsters are devices at the skin exit site that secure the G-tube to the abdominal wall and prevent its inward migration (**Figure 82-4**). Surgical gastrostomies frequently rely on only a silk suture. PEGs typically use a T-bar or retention disk. The external bolster has little impact on the function of the G-tube or the technique used to place it. The external bolster may cause the G-tube to kink, fracture, or clog if it is too tight. An external bolster can pull the internal bolster too tightly toward itself and cause stomach wall and/or abdominal wall necrosis. The G-tube may migrate inward with peristalsis and cause a bowel obstruction if the external bolster is too loose. Inappropriate care of the external bolster may lead to problems that contribute to the need for replacement, although it does not affect the ability to remove the G-tube. Identification and correction of problems with the external bolster can prevent unnecessary damage to the G-tube.

The external end of the G-tube contains the port(s) to access the lumen(s). Many tubes have a Y port, with one port for enteral feedings and a pop-off valve port to access a balloon (**Figure 82-4**). Some tubes have multiple ports to access each separate lumen that is designated for a specific purpose (e.g., medication administration or feeding). Others have a suction port for gastric suctioning and a port for distal feeding.

Some manufacturers now supply skin-level devices to improve patient comfort and acceptance. These are also referred to as low-profile systems or buttons. These tubes combine the external access port and the external bolster to provide a more cosmetically appealing look without a dangling tube.

INDICATIONS

There is no need for routine removal or replacement of G-tubes. The most common indication for G-tube replacement is accidental removal. G-tubes occasionally require replacement because they wear out, kink, or fracture. They should be replaced if the lumen becomes clogged with precipitate and cannot be unclogged. Most of these problems can be avoided with diligent care of the G-tube. Feedings should never be forced, and this is a common error that can weaken the tube. The feeding tube should be flushed with water after each use. Medications should never be mixed with enteral feeding solutions. Proper care of the G-tube should prevent premature loss. **Family members and health care providers should**

receive detailed instructions regarding G-tube management to avoid common problems.

CONTRAINDICATIONS

A damaged, malfunctioning, or displaced G-tube should be replaced as soon as possible, with a few exceptions. **The existing tube should be left in place if the tract is immature.** Premature removal of a tube in an immature tract, particularly if it is endoscopically placed, can lead to gastric spillage and peritonitis. The exact time for a tract to mature depends on the procedure used and the patient's nutritional status. A conservative approach is to consider any tract less than 4 weeks old to be immature. The specialist who performed the original procedure should be consulted prior to any manipulation of the immature tract. G-tube removal begins with deflating the balloon, if one exists. Then, while providing traction on the tube, press a flat, gloved hand against the abdominal wall for countertraction. The tube should slide out with minimal resistance. **Abort the removal if significant resistant is felt as an internal ring or bolster that requires endoscopic removal may exist.**

The G-tube and tract should be left alone and a Surgeon consulted if a patient has peritonitis at the time of presentation. If the patient has acute abdominal pain after manipulation of a gastrostomy site, feedings should be withheld until an investigation determines the source of the problem. **Do not manipulate or change the G-tube if the patient has pain at the skin entry site or with movement of the tube.** This may signify an underlying abscess, infection, or intraabdominal pathology.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Commercial replacement G-tube kits
- Foley catheter of a similar caliber as the original tube
- 20 mL syringe with saline to fill the Foley balloon
- Water-soluble lubricant
- Toomey syringe or bulb syringe to aspirate gastric contents
- Some form of external bolster (see text below)
- Adapter to cap off Foley catheter or attach it to feeding assembly
- Gloves

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. This is important in case the track is lost, the G-tube cannot be placed into the stomach, or complications result. Teach the parent or caregiver to replace a displaced tube to keep the stoma open.

G-tube replacement can usually be accomplished with little preparation or anesthesia. Place the patient supine. Clean the skin surrounding the entry site of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Anesthesia should not be necessary, as the gastrostomy site should not be tender. **Significant pain at the site may signify an infection, abscess, or intraabdominal pathology. The G-tube should not be manipulated if anything more than minor discomfort occurs.** Small children or anxious patients may benefit from mild sedation.

TECHNIQUES

The technique for replacing a G-tube will depend on the original procedure used to place the tube, the maturity of the tract, and the nature of the internal bolster. Obtain as much information as

possible about the age and nature of the existing tube. The following discussion reviews the procedure for replacing G-tubes in mature tracts, factors to consider prior to removing an existing but dysfunctional tube, and techniques to use in fashioning replacement systems.

REPLACING A DISLODGED G-TUBE

Every effort should be made to replace a dislodged G-tube as soon as possible. Gastrostomy sites begin to close as soon as the tube is removed. The tract will close within hours to days depending on its age, maturation, and size of the tube. An original tube in good condition can simply be reinserted to stent the tract until a permanent replacement is found. A commercially available replacement that is compatible with the original tube may be used. Foley catheters are simple to use, are widely available, and function well as temporary replacements.^{14,20-22}

Select a tube of similar caliber to the patient's G-tube. A Foley catheter is most commonly used. A decision regarding the choice of external fixation should be made and the tube adapted appropriately prior to its insertion (see discussion below). Lubricate the replacement tube liberally. Gently insert the replacement tube through the tract. **Do not advance the tube against any significant resistance. Advancement against more than mild resistance can result in complications.** Aspirate gastric contents to confirm proper placement. Inflate the Foley catheter balloon with saline. Pull the Foley catheter snug to lodge the balloon immediately behind the anterior abdominal wall. **The entire process should be relatively painless and should not require dissection or force.** Inject the feeding port with water-soluble contrast and obtain a plain radiograph to confirm proper placement.²³

A few types of feeding tubes merit special attention. Most gastrostomies have a short and direct route to the stomach. The Witzel uses a more circuitous tunnel and a smaller tube. The tract may be difficult to maneuver. Consult a Surgeon when problems replacing a surgically placed G-tube arise.

Not all feeding tubes terminate in the stomach. The feeding tube sometimes enters the stomach, travels through the pylorus and duodenum, and terminates in the proximal jejunum. The tract may be stented with a replacement G-tube if a patient is known to have a jejunostomy (i.e., percutaneous endoscopic jejunostomy or PEJ). More information should be obtained prior to resuming feedings.

Some catheters are not intended to be replaceable. Small needle jejunostomies may use 5 to 7 French catheters. There is little one can do to correct a catheter that has become disrupted or occluded. Consult with the patient's Primary Care Physician to discuss the options for management and follow-up.

PLACING AN EXTERNAL BOLSTER

After the successful insertion of a replacement tube, it needs to be secured in place.²⁴ The tube should be kept 90° relative to the skin and fixed in some way to prevent migration into the distal bowel. A short-term solution is to dress the site with 4×4 gauze squares. Build the gauze up along the exit site to create a pyramid-shaped dressing several inches high. A strip of urethane foam can be used to bolster the tube (Figure 82-6A).²⁵ A 3 cm section of latex tubing can be wrapped about the base of the G-tube and secured with a plastic cable tie (Figure 82-6B).²⁶ A modification to a Foley catheter uses a retention disk and a plastic ring from a nasogastric tube to secure the Foley catheter (Figure 82-6C).²²

Another option is to secure and bolster the tube with a suture (Figure 82-7). Some prefer to inject local anesthetic solution subcutaneously to minimize the discomfort of placing the single suture. Others believe placing the one suture is equal to the pain of injection

FIGURE 82-6. Types of external bolsters. **A.** Urethane foam dressing. **B.** Latex tubing wrapped about the base of the tube and secured with a plastic cable tie. **C.** A Foley catheter modified with a retention disk and plastic ring.

of the local anesthetic agent and do not use it. This decision should be decided on a case-by-case basis after a discussion with the patient and/or their representative. Place a suture using a large bite of tissue near the skin exit site. This serves as a retention suture. Leave an open loop of 1 to 2 cm between the skin and the knot to avoid unnecessary traction on the skin. Wrap the ends of the suture up the G-tube in a laddered fashion and tie them securely. This method allows some room for the G-tube to move while preventing inward migration as the patient changes position.

These techniques are adequate for short-term use. A more permanent form of external fixation is desirable. External bolsters have

FIGURE 82-7. Simple external fixation using a silk suture laddered up the G-tube.

FIGURE 82-8. Fashioning an external bolster from a latex tube and a Foley catheter. **A.** The 3 cm piece of latex tube is folded and cut. **B.** A hemostat is inserted through the latex T-bar and grasps the distal end of the Foley catheter. **C.** The latex tube T-bar is advanced onto the catheter and pulled into position. **D.** The modified Foley catheter with a latex T-bar.

been described that can be fashioned from materials available in most health care facilities. A T-bar external bolster can be made by cutting a 3 cm piece of tubing from a latex or silicone Foley catheter or feeding tube (**Figure 82-8**).²⁰ Fold the piece of tubing in half. Make two diamond-shaped cuts placed on the sides of the fold and opposite each other (**Figure 82-8A**). Insert a hemostat through the holes and gently grasp the replacement G-tube (**Figure 82-8B**). **Do not grasp and damage the balloon.** Slide the latex T-bar along the G-tube (**Figures 82-8C and 82-8D**). The latex T-bar must be snug enough to prevent migration but not so snug as to compress the G-tube lumen and disrupt function. Position the latex T-bar so that it is about 0.5 to 1.0 cm from the skin surface after placement of the G-tube.

There are several commercially available products designed specifically for replacement gastrostomies. They are convenient, but disadvantages do exist. They are expensive, may not be compatible with the original tube, and may not be on hand when needed.

Confirm and secure the clamp end of the replacement G-tube or fit it with an appropriate feeding adapter. Some tubes use the replaceable Lopez valve (**Figure 82-9**). Other G-tubes have the valve built in.

NONFUNCTIONING G-TUBES

A patient may present with a clogged, leaking, cracked, or fractured G-tube. **Numerous factors should be considered prior to removing any existing tube.** Is the tract mature? Is replacement necessary, or can other measures remedy the problem? What is the type of internal bolster, and can it be removed by external traction? **The most important factor is the age and maturity of the tract.** Premature removal of the G-tube from a fresh tract may lead to

peritoneal contamination with gastric contents and peritonitis. A new gastrostomy site should not be manipulated without consultation with the specialist who placed the original tube. A malfunctioning tube may have to remain in place to stent a fresh tract while alternative methods of nutritional support are provided to the patient.

The underlying problem with a nonfunctioning G-tube should be investigated prior to its removal and replacement. A fractured tube or a tube with a ruptured balloon will need replacement. A kinked tube may only need revision of the external bolster. A clogged tube should first be irrigated with warm tap water, saline, or a carbonated beverage to open the lumen.^{27,28} **Do not force the irrigation fluid into the G-tube. It may rupture and injure the patient.** A variety of other options may be tried to open a clogged G-tube. These include the instillation of enzymes to break up or dislodge the clog with an endoscopic snare, biopsy forceps, or Fogarty

FIGURE 82-9. The Lopez valve.

catheter.²⁷⁻³⁰ The latter methods are usually performed by a consultant and not the Emergency Physician.

A simple, quick, inexpensive, and easy to use device has been developed to declog a G-tube (Feeding Tube DeClogger, Bionix Development Corp., Toledo, OH). These are flexible plastic wands with a basic screw thread (**Figure 82-10**). They come in lengths for gastrostomy and jejunostomy tubes and in various sizes (12 to 24 French). Insert the DeClogger into the feeding port (**Figure 82-11**). Slowly advance

it while rotating clockwise. Advance the DeClogger until it is fully inserted. Slowly remove the DeClogger from the feeding port. Aspirate and insufflate air to confirm the G-tube patency. This device may prevent the time and expense of replacing a clogged feeding tube. The patient and/or their caretaker can be taught how to use this device at home, which may prevent a trip to an office or Emergency Department.

The decision to replace a G-tube requires the Emergency Physician to obtain information regarding the type of tube in place.

FIGURE 82-11. Using the Bionix Feeding Tube DeClogger. **A.** The clogged G-tube. **B.** The DeClogger is slowly advanced through the clog while being rotated clockwise. **C.** The clog has been removed and free flow reestablished.

Many are removable by gentle external traction. **Never apply more than gentle traction when removing a G-tube.** Simply deflating the internal bolster balloon will allow the G-tube to be removed. Other bolsters such as soft domes and T-bars may deform easily with gentle constant traction. **If gentle traction is not sufficient to remove the G-tube, either the internal bolster is not intended to be removed externally or it may have become embedded within the gastric wall.** Consult the physician who placed the tube if difficulty occurs when trying to remove a G-tube. The most likely problems and alternate solutions are discussed below.

THE BALLOON DOES NOT DEFLATE

The balloon may not deflate if the balloon inflation port is clogged or damaged. There are four options to remedy this situation. Simply cutting the G-tube may allow the balloon to deflate on its own. Cut the G-tube close to the ports. Maintain a firm hold, manually or with a hemostat, so that the cut tube does not migrate inside the patient and require endoscopic removal. The G-tube can be pulled taut to the skin and a needle advanced into the tract to puncture the balloon.³¹⁻³³ A guidewire may be advanced through the balloon port to puncture and deflate the balloon.³⁴ The balloon may have to be ruptured internally with an endoscopic snare.

THE G-TUBE DOES NOT WITHDRAW WITH EASE

Simply cutting the feeding tube at the skin level and pushing the remaining tube through the tract and into the stomach is not universally recommended. This allows the internal components to pass through the patient's gastrointestinal tract. Retained G-tube components have been known to cause bowel obstructions and perforations.³⁵ Most G-tubes pass without incident.³⁵ This procedure works for many types of G-tubes. It is not clear that this is a safe option for balloon bolsters that have not been deflated. **This option should be used only if a Primary Care Provider agrees with that choice and is available to follow the patient until the contents have passed.** Radiopaque components can be followed by plain radiographs at 24 to 48 hour intervals. The gastrostomy "hardware" may have to be retrieved endoscopically or surgically if it fails to pass within 2 to 3 weeks or the patient experiences obstructive symptoms. This option is not recommended for small children under the age of 6 years or weighing less than 20 kg.³⁶ These patients have a greater risk for complications.³⁶

REMOVAL OF THE G-TUBE FROM A FRESH OR IMMATURE TRACT

The disruption of a fresh tract raises the possibility of gastric spillage and peritonitis. All enteral feedings should be discontinued and the patient observed for the development of peritonitis. Replacement options have been described. The tract may be allowed to close spontaneously and a replacement PEG placed in 7 to 10 days if the patient remains well.³⁷ Endoscopy can attempt to reintroduce a replacement tube under direct visualization through the original tract.³⁸ A Surgeon should be consulted and laparotomy considered if peritonitis develops. The Surgeon may choose to place a surgical gastrostomy. **Attempts to replace a removed tube from a fresh or immature tract should not be made in the Emergency Department.**

THE TRACT HAS CLOSED

A gastrostomy tract that is not stented will begin to close within hours.³⁹ A lost tract may require a repeat procedure. This problem requires consultation with an Endoscopist. Dilation of a closing gastrostomy site has been described using filiform catheters and followers or urethral sounds adapted from Urology.⁴⁰ **This procedure should be performed with caution as it can result in numerous complications.** Interventional Radiologists can often replace dislodged tubes using special techniques.

EARLY BALLOON RUPTURE OF AN INTACT G-TUBE IN AN IMMATURE TRACT

The tract is stented but there is the risk of gastric leakage around a deflated balloon. Consider replacement using a guidewire to exchange the G-tube.⁴¹ This technique is performed using endoscopic guidance to snare the guidewire and withdraw the original G-tube.

ASSESSMENT

The replacement G-tube should be placed to allow gravity drainage, or the stomach contents should be aspirated. Use of the G-tube can be resumed if there is free flow of gastric contents. Its position should be confirmed radiographically if there was any difficulty with placement of the G-tube or if the return is equivocal. A small amount of water-soluble radiopaque contrast should be administered through the G-tube and a plain radiograph obtained. Normal G-tube placement will show intraluminal contrast. **Any extravasation of contrast is abnormal and requires enteral feedings to be withheld and a Surgeon to be consulted.** The patient will require hospitalization for parenteral antibiotics, observation, and bowel rest until the tract heals. Some physicians elect to evaluate all replaced G-tubes radiographically prior to their use. Doing so is theoretically harmless to the patient and causes no complications. This process cannot be routinely recommended as it is time-consuming and expensive.^{42,43}

AFTERCARE

Routine maintenance can resume after successful replacement of the G-tube. Any factors that contributed to the malfunction should be addressed to prevent a recurrence. **The patient and/or their caregivers should be taught the proper care and maintenance of a G-tube.**^{27,44} The patient should follow up with their primary physician in 24 to 48 hours for evaluation, removal of the temporary tube, and placement of a G-tube. Instruct the patient to immediately return to the Emergency Department if they develop a fever, abdominal pain, nausea, or vomiting.

COMPLICATIONS

A variety of complications may accompany the initial insertion of a G-tube (**Table 82-1**).^{8,12,45,46} Replacement at a mature site should be relatively free of problems. Excessive force during replacement can disrupt the tract. A misdirected tube may end in a blind pouch or the peritoneal cavity if the stomach separates from the anterior abdominal wall. Installation of enteral feedings intraperitoneally will cause a chemical peritonitis. This should be suspected if there is poor return from the replaced G-tube, difficulty installing feedings, or the patient develops pain or fever after the procedure. Peritonitis is preventable if proper positioning is confirmed prior to using the replacement tube.⁴⁷

A replacement G-tube must be sufficiently secured externally so that the effect of peristalsis does not carry it distally.²⁴ This is particularly true of balloon-tipped tubes. A G-tube that migrates past the pylorus can cause bowel obstructions and perforations.^{8,12} This can be avoided by carefully securing the replacement G-tube with an external device or suturing it securely to the skin.

Always advance the Foley catheter into the stomach before carefully and slowly inflating the balloon. Inflation of the balloon within the gastrocutaneous tract can result in hemorrhage, pain, and rupture of the tract. Over-insertion of the catheter can cause the balloon to enter the esophagus, duodenum, or gastroesophageal

junction. These structures can rupture when the balloon is inflated. These complications can be avoided by inserting the Foley catheter 8 to 10 cm, slowly inflating the balloon, and not inflating the balloon to its maximal volume.

A mature gastrostomy tract begins to close as soon as the tube is removed. The tract narrows without the presence of the G-tube to keep it patent. Replace the G-tube as soon as possible. **Never force a tube through the tract.** This can result in bleeding, gastric perforation, intraperitoneal penetration, pain, and the formation of a false passage. **Pass a smaller-size tube if necessary to reestablish the tract and maintain its patency.**

An indwelling or replacement G-tube may result in a gastric outlet obstruction. The patient usually presents with distention of the stomach and vomiting. Immediately and gently pull back on the G-tube until it is snug against the abdominal wall. Secure the G-tube with an external bolster. Observe the patient for resolution of their symptoms and any complications.

The skin exit site may become edematous, erythematous, and tender. A simple cellulitis should be managed with oral antibiotics and local wound care. Failure to resolve with antibiotics alone may suggest the presence of an abscess, and further imaging or drainage may be required. A dermatitis can result from leakage of gastric contents around the G-tube. Ensure that the internal bolster is secured against the anterior abdominal wall. If the leakage persists, replace the G-tube with a larger one that occludes the tract. Local wound care is all that is necessary once the problem with the G-tube is corrected. Hypersensitivity to the adhesive, cleansing solutions, or the G-tube itself may occasionally develop. The use of different materials and topical corticosteroids will correct this problem. A yeast infection (e.g., *Candida albicans*) appears erythematous and moist with satellite lesions. Topical antifungal creams and local wound care will alleviate the yeast infection. Granulation tissue around the stoma can be eliminated by coagulation with silver nitrate sticks. The patient should follow up with their primary physician in 24 to 48 hours for a reevaluation of all these clinical entities.

TABLE 82-1 Troubleshooting Enterostomy Tubes

Problem	Possible cause(s)	Action(s)
Vomiting	Balloon obstruction Balloon malposition	Check tube length Pull back tube Check placement KUB without contrast
Diarrhea	Fistula	Contrast study for fistula evaluation
Tube comes out in ≤ 4 weeks	< 2 weeks	Call Interventional Radiology Do not replace
Tube comes out in ≥ 4 weeks	> 4–6 weeks	Place urinary catheter in stoma Confirm placement with contrast study
Tube clogged	Review medication list for possible causes: ciprofloxacin suspension, lactulose, Kayexalate, tube feeds, etc.	Flush with warm water Flush with carbonated beverage Consider pancrelipase
Tube leaking	Check connection joints Look for holes in tube	Seal with tape Replace tube
Pain or resistance with feedings	Buried bumper syndrome Peristomal leak leading to erosion of internal bolster Cellulitis	Contrast study Tube replacement Start antibiotics
Erythema at tube site	Increased mobility Skin sensitivity to tape Leakage of gastric acid Granulation tissue Cellulitis	Secure tube Change tape Add acid-blocking agent Cauterize with silver nitrate Topical steroids Start antibiotics
Abdominal pain and fever	Peritonitis	Contrast imaging IV ABx, IVF Cessation of TF Surgical consult Nasogastric suction
Respiratory distress	Aspiration Slipped Nissen *Pediatric patient who has not had antireflux surgery	Specialty consult Fundoplication Gastrojejunostomy

ABx, antibiotics; IV, intravenous; IVF, intravenous fluids; KUB, kidneys, ureter, bladder; TF, tube feedings.

PEDIATRIC CONSIDERATIONS

Pediatric patients face many of the same complications as adult patients with G-tubes.⁴⁷⁻⁵⁰ There are some special considerations with G-tube placement and tube sizing that require some caution in pediatric patients. There are important questions to ask the caregiver when a feeding tube is dislodged or not functioning properly or there is concern about the site (e.g., bleeding, leaking, redness). These include the timing of initial placement of the tube, size of the tube, type of tube (e.g., button, PEG, mushroom tip, GJ), and how long it has been dislodged (if applicable).⁴⁶ The integrity of the tract between stoma and stomach is usually well formed by 4 to 6 weeks postoperatively. Note the length of the tube at the level of the skin. This might be an indicator of inward or outward movement of the tube. Note the balloon-filling instructions on the tube itself. The G-tube should note how many milliliters would fill the balloon. A small child may require 3 mL of air, while a larger child may require 5 mL of air to fill the G-tube balloon.^{46,49,51}

Dislodgement of G-tubes is the leading reason for presentation to the Emergency Department. It accounts for approximately 60% of all Emergency Department visits related to G-tubes. Clogging of the feeding tube can occur. This is much more common when feeding via GJ-tubes versus G-tubes. The smaller caliber and extended length of GJ-tubes can cause increased obstruction of the lumen. GJ-tubes have a proximal port entering the stomach and a more distal port that feeds directly into the jejunum. Medications and formulas can cause sludging within the lumen of G-tubes and GJ-tubes. The tube should be flushed with saline after these are administered. Some children have GJ-tubes placed as an alternative for fundoplication

to prevent aspiration pneumonia. A child with a G-tube who has not had antireflux surgery (e.g., Nissen fundoplication) is at risk for aspiration pneumonia. Aspiration should be considered as a cause of respiratory distress.³³

Migration of a G-tube can occur and lead to intestinal obstruction. The average length of the traditional G-tube or GJ-tube that protrudes from the stoma at the skin level is between 4 and 6 cm. This may be shorter for very small children and infants. Check the centimeter markings on the outside of the tube to provide evidence that a tube has migrated inward. Pulling back on a G-tube until the balloon is against the abdominal wall can relieve obstruction due to migration. G-tubes with a length of external tubing are initially placed then switched to a button-type tube that sits flatter to the skin. Button-type tubes have a decreased risk of dislodgement from pulling or migration distally into the gastrointestinal tract than traditional G-tubes.^{18,19,52-55}

G-TUBE REPLACEMENT

Replace the tube with one the same size as the one that was dislodged. Have a smaller one available in case the stoma has closed. Sometimes the original-sized tube does not fit into a narrowed stoma. Start with a smaller-sized Foley or replacement tube and dilate the tract using progressively larger tubes or a set of Hegar dilators until the original tube size can be used. Replacement tubes can be a simple Foley catheter, G-tube, or button G-tube. Do not force the replacement tubes to avoid creating a false tract.⁵⁶ Clinical confirmation of correct placement can be checked by suctioning gastric contents, checking the pH with litmus paper, or dye studies with a small amount of radiocontrast material (e.g., 5 to 10 mL) followed with plain films. The tube is appropriately positioned on the radiograph if the outline of the stomach, or jejunum if there is a jejunal tube, is clearly seen.⁵⁶ The use of radiologic dye studies to confirm placement is variable among institutions, and this routine practice may not be necessary if one can clinically prove the tube is properly placed.

GASTROJEJUNAL TUBE REPLACEMENT

The patient may not know what type of tube they have. G-tubes typically have two ports, and GJ-tubes have three ports. Medications requiring an acidic environment for ideal absorption are usually given via the gastric port, whereas continuous drip feeds are given via the jejunal port. Bolus feeding into the jejunum is not feasible. The osmotic load leads to diarrhea. Parents or caregivers will be able to tell you whether they drip or bolus feed.

Contact an Interventional Radiologist to replace the tube under fluoroscopy or transfer the patient to an appropriate center for tube placement for GJ-tube dislodgment. Place a small catheter in the stoma to temporarily maintain patency until a more definitive feeding tube can be placed.⁵²

CORRECTING LEAKAGE AT THE STOMA SITE

It is not recommended when there is leakage at the stoma site to replace the tube with a larger one and expand the stoma.⁶ The correct probe position and balloon inflation should be verified by pulling the tube until the balloon is snug against the internal stomach wall.^{57,58} A new tube can then be positioned through the same site when the leakage persists for several days. The G-tube can be removed in consultation with the specialist who placed the tube and allow partial stoma closure.⁴²

Irritation from gastric content leakage can sometimes be mitigated by ensuring that the tube is directly against the anterior stomach

wall. This can be done by first ensuring that the balloon is inflated, gently pulling the G-tube portion outward until resistance is met, and then pushing the external retention disc down toward the skin. This helps to seal any defects in the space between the stoma and the part of the G-tube within the stomach lumen to prevent further leakage of stomach contents. Place a gauze pad between the disc and the abdominal wall skin. The application of topical sucralfate, magnesium hydroxide, or menthol/zinc oxide may be used to relieve the irritation of acidic stomach contents on the skin.⁵⁹

SUMMARY

G-tubes result in a simple fibrous tract connecting a feeding tube to the stomach. A mature tract can be safely and easily manipulated. Problems with an immature tract should prompt consultation. Percutaneous radiologically placed tubes are ultimately replaced by Interventional Radiology given its indication of placement and anatomical location. Techniques for the basic maintenance and repair of G-tubes are straightforward. Patients with dislodged G-tubes that have been replaced with Foley catheters, G-tubes, or buttons can be discharged home to follow-up with the service that placed the tube if the patient does not require admission. Familiarity with the procedures and equipment used to establish gastrostomies will help the Emergency Physician solve common G-tube problems and intervene in an appropriate and timely manner.

Paracentesis

Alex Koo and Ryan Walsh

INTRODUCTION

Ascites is an abnormal accumulation of fluid in the abdominal cavity (**Figure 83-1**). It has important implications diagnostically, prognostically, and therapeutically. Cirrhosis of the liver is usually related to alcoholism and accounts for 75% of cases of ascites.^{1,2} Malignancy accounts for an additional 10% to 12% and cardiac failure for another 5%. The remaining cases have a variety of etiologies. The physical examination is not very reliable when it comes to detecting ascites, making paracentesis and ultrasound (US) important clinical tools.³ US-guided paracentesis has two key benefits. It facilitates

FIGURE 83-1. Computed tomography image of the abdomen with ascites (arrow). (Used from www.commonswikimedia.org.)

performance of the procedure and identifies patients in whom the procedure is not warranted or could potentially be harmful.⁴

Peritoneal aspiration of ascitic fluid or paracentesis was first described in the early twentieth century.⁵ Paracentesis fell out of favor in the 1950s with the introduction of diuretics and the fear of procedure-related complications and was replaced by medical management. Large-bore needles were being used at that time, and complication rates were significant. Clinical studies published in the late 1980s demonstrated that performing a paracentesis was a safe procedure.^{6,7} A paracentesis is now common in Emergency Departments.

Paracentesis is an important diagnostic tool for patients with new-onset ascites to determine its etiology and in patients with long-standing ascites to detect the presence of an infection. Spontaneous bacterial peritonitis (SBP) can be a very subtle disease. Infection occurs in as many as 27% of cirrhosis patients admitted for evaluation of symptoms associated with their ascites.⁸ It is well known that some patients with SBP are asymptomatic.⁹ **This makes peritoneal fluid aspiration, analysis, and cultures imperative.**¹⁰ Large volumes of ascitic fluid can be removed therapeutically to improve a patient's respiratory status and comfort level from the pressure of tense ascites. This often occurs in patients with end-stage liver disease and some cases of malignancy. Malignant ascites may occur with carcinomas (e.g., breast, colon, ovary, pancreas, stomach, and testes), lymphomas, and sarcomas.

ANATOMY AND PATHOPHYSIOLOGY

The abdominal cavity is partially lined by a serous membrane known as the peritoneum. The abdominal cavity is protected from the environment by the abdominal wall musculature, fat, and skin. The peritoneum serves as protection for its encased organs, secretes

nutrients, and secretes proteins. Intraperitoneal organs include the stomach, first portion of the duodenum, jejunum, ileum, appendix, transverse colon, sigmoid colon, part of the rectum, liver, spleen, and the tail of the pancreas. The right and left rectus muscles are nourished by the epigastric vessels. The epigastric vessels meet in the midline at the avascular linea alba. The umbilicus is located along the lower portion of the linea alba. The layers of the anterior abdominal wall structures vary above and below the level of the anterior superior iliac spine (Figure 83-2).

The anatomy of the abdominal cavity is consistent among individuals. The liver sits in the upper right quadrant. Studies demonstrate that estimation of size through physical examination is inaccurate, even with expert evaluation.¹¹⁻¹³ The consistency of the liver may confer information on cirrhosis or masses.¹⁴ The spleen is normally contained in the upper left quadrant. It can extend into the left lower quadrant of the abdomen when enlarged. The physical examination is not sensitive but specific for splenomegaly when the spleen is palpable. The diagnosis of hepatomegaly or splenomegaly can be aided with the use of US.¹⁵ The intestines occupy most of the abdominal cavity and are not rigidly adherent, allowing them to move about in the abdominal cavity. The bladder sits inferior to the abdominal cavity. The bladder can enter the abdomen when it is distended with urine.

There is a potential space intraperitoneally that is considered abnormal when there is fluid present. Ascitic fluid can be found anywhere in the peritoneal cavity. The location of the ascitic fluid depends primarily on the amount of fluid present and the patient's position. Fluid follows the law of gravity and collects in the most dependent areas. Small amounts of fluid generally accumulate first in the hepatorenal recess (i.e., Morrison's pouch) while the patient is lying supine. Large amounts of fluid can be found bathing the intestines (Figure 83-3). There can be distinct pockets of fluid in areas

FIGURE 83-2. The layers of the anterior abdominal wall vary above (A) and below (B) the level of the anterior superior iliac spine.

FIGURE 83-3. US of the abdomen demonstrating loops of intestine floating in ascitic fluid. (Used with permission from reference 23.)

of intestine adhesions or scarring. These localized areas of fluid are typically found in patients who have infections, previous surgery, or trauma.

Paracentesis is easily performed blindly. **US can provide several benefits.** US is diagnostically useful to ensure there is enough fluid to perform a paracentesis.¹¹ It will identify and help avoid solid organs, masses, and vascular structures. US is sensitive for hepatomegaly and splenomegaly.^{14,15} US can identify areas where the intestine is adherent to the abdominal wall from adhesions and puncture should not occur. US can measure the soft tissue thickness from the skin to the peritoneum, locate the thinnest entry point, and determine the needle length required to perform the procedure in obese patients. US can be used to position the patient so that the maximum amount of fluid collects at the sampling site.

INDICATIONS

A paracentesis can be performed for diagnostic or therapeutic purposes. A paracentesis or “abdominal tap” is warranted in a patient with new-onset ascites to establish the etiology of the fluid. A patient with a history of ascites may need the procedure if they have associated signs and symptoms suggestive of infection (e.g., abdominal pain, dyspnea, fever, encephalopathy, peripheral leukocytosis, or renal impairment).¹⁶ A paracentesis can be performed therapeutically if medical management with diuretics has not been successful. A paracentesis may be therapeutic in patients with cardiorespiratory or gastrointestinal manifestations secondary to tense ascites. It is most commonly performed when an intraperitoneal infection is suspected. **Clinical guidelines recommend that patients with new-onset ascites admitted to the hospital undergo a paracentesis regardless of whether they have symptoms of SBP.**^{16,17} Paracentesis has been used to aid in the diagnosis of intestine perforation, hemoperitoneum due to trauma, and ruptured ectopic pregnancy. More accurate diagnostic procedures should be used rather than a paracentesis for these conditions if they are available. Paracentesis is used to manage some patients with hepatorenal syndrome in conjunction with the consultant.¹⁸

CONTRAINDICATIONS

There are no absolute contraindications to performing a paracentesis. The relative contraindications include abdominal wall cellulitis, coagulopathy, current intestine obstruction, history of

abdominal surgery, pregnancy, or thrombocytopenia. Pregnancy is listed because the gravid uterus may fill the space where the procedure is normally performed. **A paracentesis should be performed superior to the uterine fundus. Avoid sites of previous surgical incisions.** Adhesions may fix the intestine wall to the abdominal wall and increase the possibility of perforation.

Many patients who are subjected to a paracentesis have underlying liver disease and resultant coagulopathies. Historically, some have advocated patients with thrombocytopenia or an abnormal international normalized ratio (INR) receive platelet transfusions or factor replacement prior to performing a paracentesis. This practice is controversial, and there are no controlled data to support these contentions.^{19,20}

One large retrospective study of 4729 paracenteses performed in patients with coagulopathies and/or thrombocytopenias found very low rates of severe hemorrhage (0.19%), defined by hemodynamic instability or a decrease in hemoglobin of > 1.5 gm/dL, and death (0.016%).²¹ Bleeding was unrelated to the elevation in INR and the level of thrombocytopenia. Patients with prophylactic transfusion of platelets or plasma had similar outcomes to those without prophylactic transfusion.

EQUIPMENT

- Protective eyewear
- Sterile gloves and gown
- Cap and mask
- Povidone iodine or chlorhexidine solution
- Sterile 4×4 gauze
- Sterile drape
- Local anesthetic solution with epinephrine
- 25 or 27 gauge needle to anesthetize the skin
- Large syringe(s) for fluid collection (20 to 60 mL)
- Intravenous tubing or blood collection tubing if vacuum bottles are being used
- Collection bottles (vacuum) or collection bag
- Adhesive dressing
- Three-way stopcock²²
- Blood collection tubes for white blood cell count, electrolytes, albumin, pH, etc.
- Blood culture bottles (aerobic and anaerobic)
- Sterile specimen container for cytology (optional)
- US machine
- US transducer, 3.5 to 5 MHz curvilinear and 8 to 12 MHz linear
- Sterile US gel
- Sterile US transducer cover

CHOICE OF NEEDLE OPTIONS

- 18 to 22 gauge needle, 3½ inch needle or spinal needle
- Seldinger-type guidewire kit
- Catheter-through-the-needle
- Catheter-over-the-needle (i.e., angiocatheter), consider Caldwell needle

Commercially available paracentesis kits are available (**Figure 83-4**). These contain all the required equipment except the collection bottles. They include the sterile drapes and local anesthetic solution. These are convenient and relatively inexpensive.

A

B

FIGURE 83-4. Commercially available paracentesis kits. **A.** The Arrow kit (Teleflex Inc., Morrisville, NC). **B.** The Safety-Centesis kit (Becton Dickinson, Franklin Lakes, NJ). (Photos courtesy of Jason Williams, MD, and www.proceduralist.org.)

A general-purpose curvilinear or phased-array US transducer provides the best combination of penetration and field of view into the abdomen. A linear transducer can be used for children, small adults, and thin patients. Use the 3.5 to 5 MHz curvilinear transducer to locate the ascites if it is small.²³ Use the 8 to 12 MHz high-frequency linear transducer for the procedure.²³

Some patients have indwelling subcutaneous ports. These patients have ports for frequent access to the abdomen. This includes patients

receiving antibiotics, chemotherapeutics, and frequent paracenteses. Refer to Chapter 66 for accessing these devices.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain an informed consent for the procedure. The patient's bladder should be empty. Use a US machine to check

FIGURE 83-5. Needle insertion sites to perform a paracentesis (indicated by a red ⊗). The preferred site is in the midline and 2 cm below the umbilicus. Alternative sites are just medial and 4 to 5 cm above the anterior superior iliac spines.

for a full bladder or place a Foley catheter to decompress the bladder if the patient is unable to urinate voluntarily. Placement of a nasogastric tube can be considered, although it is not routine. It prevents an iatrogenic perforation if the stomach is dilated or if a concomitant intestine obstruction is present. It is recommended if the blind technique is performed to avoid a perforation.

There are two recommended areas of entry for the paracentesis needle (Figure 83-5). The first site is in the midline and 2 cm below the umbilicus through the avascular linea alba. Alternatively, the region 4 to 5 cm superior and just medial to the anterior superior iliac spine in one of the lower quadrants may be used. **This location should be lateral to the rectus abdominis muscle to avoid injury to the inferior epigastric artery, which runs vertically along the muscle sheath.** Some Emergency Physicians choose the right lower quadrant to avoid the sigmoid colon and spleen. Others choose the left lower quadrant to avoid the cecum and liver. Remember to exercise caution in the regions of caput medusae, prominent veins, scars, over an area of inflamed or infected skin to minimize complications. US-assisted paracentesis is recommended if a US machine is readily available. US can assist in identifying the ideal fluid pocket and hopefully avoid a “dry tap.”²⁴

Place the patient sitting 45° upright for a midline approach. This positioning can be used for the right or left lower quadrant approach if there is ample ascites. Lying in the right lateral decubitus position for a right lower quadrant approach or lying in the left lateral decubitus position for a left lower quadrant approach increases dependency of the ascites to a desirable quadrant while displacing the

intestine superiorly. Another position one might consider is having the patient assume a hand-knee or “crawling” position. This position is awkward for the Emergency Physician performing the procedure. Remember that the fluid will pool in dependent areas and the intestine will float on top of it, barring any adhesions or masses.

Prepare the patient. Clean the skin around the chosen puncture site of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to delineate a sterile field. Don a cap, mask, sterile gloves, and sterile gown. **Perform the paracentesis using strict sterile technique.** Inject 2 to 5 mL of local anesthetic solution subcutaneously and along the needle insertion tract. Allow 3 to 5 minutes for the local anesthetic to take effect.

TECHNIQUES

Z-TRACK TECHNIQUE

A “Z-track” is used to decrease the possibility of an ascitic fluid leak, especially in patients with tense ascites (Figure 83-6). This is the preferred method for inserting the needle. This technique should be followed when using the other techniques described below. Apply traction on the skin 2 cm cephalad or caudad to the needle insertion site so that the skin is pulled taut when the needle enters the peritoneum (Figures 83-6A and 83-6B). The skin will return to its normal position when the tension is released and seals off the pathway of the paracentesis needle.

Apply an 18 to 22 gauge, 3½ inch needle or spinal needle to a 60 mL syringe. Slowly insert and advance the needle perpendicular to the skin (Figure 83-6A) or at 45° to the skin and aimed caudally (Figure 83-6B). Apply negative pressure to the syringe as it is being advanced. A loss of resistance will be felt as the needle enters the peritoneal cavity. Stop advancing the needle when ascitic fluid enters the syringe. Continue to aspirate until the syringe is one-half to three-fourths filled with fluid. Depending on the size of syringe, consider using a three-way stopcock so syringes can be removed as they are filled.

The omentum, a loop of intestine, peritoneal fat, or other tissue may be occluding the needle tip if ascitic fluid suddenly stops flowing into the syringe. Release the plunger of the syringe. Reattempt to aspirate. Inject 1 to 2 mL of ascitic fluid back into the peritoneal cavity if fluid still will not flow and then reattempt to aspirate. Reposition the needle if ascitic fluid still does not flow into the syringe. **Never reposition the needle while the sharp tip is within the peritoneal cavity. The needle can lacerate a blood vessel, the intestine, or the omentum.** Withdraw the needle to the dermis, reposition it, and then readvance it into the peritoneal cavity.

The Caldwell needle appears to be superior to a conventional angiocatheter needle when it comes to problems with fluid return. The Caldwell needle’s unique design with fenestrations on the side is believed to allow for continued flow despite occlusion of the needle tip.^{24,25}

Note the color and clarity of the ascitic fluid. Aspirate 30 to 50 mL if the procedure is being performed for diagnostic purposes. Withdraw the needle after obtaining the ascitic fluid. Immediately place the fluid into the appropriate collection tubes and culture bottles.²⁶ Hold the needle or catheter securely and remove the syringe if the reason for the paracentesis is therapeutic and there is a large collection of fluid that must be drained. An assistant can place the sample into laboratory containers. Connect the needle or catheter to intravenous tubing. Connect the other end of the intravenous tubing to a suction bottle or bag to drain off the desired amount of ascitic fluid. Remove the needle or catheter once the procedure has been completed. Removal results in the formation of the Z-track so that ascitic fluid will not leak from the skin (Figure 83-6C). Apply a

FIGURE 83-6. The Z-track. **A.** The needle is inserted perpendicular to the skin while the skin is pulled taut. **B.** Alternatively, the needle can be inserted at 45° to the skin and aimed caudally. **C.** The resultant Z-track (arrows).

bandage to the skin puncture site. Consider a compression dressing with an occlusive bandage if fluid is oozing from the puncture site.

SELDINGER TECHNIQUE

This technique allows for the placement of a catheter over a wire (**Figure 83-7**). The wire used must be longer than the catheter. The needle used to insert the wire can be short and a smaller gauge than the catheter. Materials needed for catheter insertion are commercially available in a prefabricated kit. The Seldinger technique is most commonly used for central venous catheter insertion and familiar to the Emergency Physician.

Choose the puncture site and prepare the patient for the procedure. Insert the thin-walled introducer needle in a Z-track manner while applying negative pressure to the syringe (**Figure 83-7A**). The

introducer needle has a tapered hub on the proximal end to guide the wire into the needle lumen. **Avoid using a standard hypodermic needle as it does not allow for the passage of the guidewire.** A flash of fluid in the needle hub signifies that the tip of the needle is within the peritoneal cavity (**Figure 83-7A**). Advance the needle an additional 2 to 3 mm. Hold the needle in place securely and remove the syringe.

Occlude the needle hub with a sterile gloved finger. This will prevent air from entering and ascitic fluid from exiting. Insert the guidewire through the hub of the needle (**Figure 83-7B**). Advance the guidewire to the desired depth and ensure it is at least several centimeters beyond the beveled end of the needle. **Always have at least one hand holding the guidewire to prevent it from slipping completely into the peritoneal cavity.** Hold the guidewire securely in place. Remove the needle over the guidewire (**Figure 83-7C**).

FIGURE 83-7. The Seldinger technique. **A.** The needle is advanced into the peritoneal cavity. **B.** The syringe is removed and a guidewire is inserted through the needle and into the peritoneal cavity. **C.** The needle is removed, leaving the guidewire in place. **D.** An incision is made where the guidewire enters the skin. **E.** The dilator and sheath are advanced as a unit over the guidewire. **F.** The dilator and sheath are advanced into the peritoneal cavity with a twisting motion. **G.** The guidewire and dilator are removed as a unit, leaving the sheath in place. **H.** A syringe is attached to the sheath. The aspiration of ascitic fluid confirms proper intraperitoneal placement of the sheath.

Make a small nick in the skin adjacent to the guidewire with the #11 scalpel blade included in the kit (**Figure 83-7D**). **Direct the sharp edge of the scalpel blade away from the guidewire to avoid nicking the guidewire.**

Place the dilator through the sheath or catheter to form a unit. Advance the dilator and sheath unit over the guidewire (**Figure 83-7E**). Continue to advance the dilator and sheath unit over the guidewire and into the peritoneal cavity (**Figure 83-7F**). A twisting motion may aid in its advancement through the skin and into the peritoneal cavity (**Figure 83-7F**). Advance the unit until the hub of the sheath is against the skin. Hold the hub of the sheath securely. Remove the guidewire and dilator as a unit (**Figure 83-7G**). Attach a syringe to the hub of the sheath (**Figure 83-7H**).

Aspirate fluid from the sheath to confirm intraperitoneal placement (**Figure 83-7H**). Hold the hub of the sheath securely and remove the syringe. Pass the syringe to an assistant to place the sample into laboratory containers. Connect the hub of the sheath to intravenous tubing. Connect the other end of the intravenous tubing to a suction bottle or bag to drain the desired amount of fluid. An alternative is to attach a three-way stopcock to the distal end of the intravenous tubing.²² A syringe may then be attached to the stopcock to withdraw laboratory samples or “pump out” the ascitic fluid into a nonsterile container. Remove the sheath once the procedure is completed. Apply a bandage to the skin puncture site. This technique seems complicated at first glance. It is easy to learn and can be performed in a few minutes by an experienced Emergency Physician.

CATHETER-THROUGH-THE-NEEDLE TECHNIQUE

This system is used for central venous access outside the United States. Select a catheter size that is appropriate for the patient and the site of entry. Packaged with each catheter are a needle and a needle guard. The needle will have an inner diameter that is slightly larger than the outer diameter of the catheter. The needle guard has a beveled channel in which the needle can reside. The needle guard hinges closed over the needle to hold it securely and prevent the needle from shearing the catheter.

Choose the puncture site and prepare the patient for the procedure. Place the needle on a tuberculin syringe. Insert the needle through the skin in a Z-track manner and into the peritoneal cavity while applying negative pressure to the syringe (**Figure 83-8A**). A flash of fluid in the syringe confirms that the tip of the needle is within the peritoneal cavity. Advance the needle an additional 2 to 3 mm to ensure that the tip of the needle is completely within the peritoneal cavity. Securely grasp and hold the needle with the nondominant hand. Remove the syringe with the dominant hand. Immediately place the nondominant thumb over the needle hub to prevent air from entering and fluid from exiting.

Insert the catheter through the hub of the needle (**Figure 83-8B**). Advance the catheter through the needle until the desired length of catheter is within the peritoneal cavity. **Remove the catheter and needle as a unit if the catheter will not advance. Never withdraw the catheter through the needle. The sharp bevel of the needle may cut the catheter as it is being withdrawn and result in a catheter embolism in the peritoneal cavity.**

Withdraw the needle over the catheter (**Figure 83-8C**). **Do not allow the catheter to be withdrawn through the needle.** Continue to withdraw the needle until the tip is completely outside the skin. Apply the needle guard over the needle (**Figure 83-8D**). Attach a syringe onto the hub of the catheter. Aspirate fluid from the catheter to confirm intraperitoneal placement. Hold the hub of the catheter securely and remove the syringe. Pass the syringe to an assistant to place the sample into laboratory containers. Connect the catheter to

FIGURE 83-8. The catheter-through-the-needle technique. **A.** The needle is advanced into the peritoneal cavity while maintaining negative pressure on the syringe. **B.** The syringe has been removed. The catheter is inserted through the needle. **C.** The needle is withdrawn and the catheter is left within the peritoneal cavity. **D.** A syringe is attached to the catheter and the needle guard applied. The aspiration of ascitic fluid confirms proper intraperitoneal placement of the catheter.

intravenous tubing. Connect the other end of the tubing to a suction bottle or bag to drain the desired amount of fluid. An alternative is to attach a three-way stopcock to the distal end of the tubing.²² A syringe may then be attached to the stopcock to withdraw laboratory samples or “pump out” the ascitic fluid into a nonsterile container. Remove the catheter once the procedure is completed. Apply a bandage to the skin puncture site.

The main disadvantage of this technique is the possibility of the needle tip shearing off the catheter and resulting in a catheter embolism. **This can be prevented by not withdrawing the catheter through the needle and applying the needle guard immediately after the needle is withdrawn from the skin.** Another disadvantage is that the contaminated needle must be handled to some extent, creating a potential risk for needle-stick injuries.

CATHETER-OVER-THE-NEEDLE TECHNIQUE

The catheter-over-the-needle systems are most commonly used for peripheral venous access. They are inexpensive, come in a variety of diameters and lengths, and are widely available. The catheter fits closely over a hypodermic needle. The needle and the catheter are advanced as a unit into the peritoneal cavity. Versions designed to minimize accidental needle-stick injuries are available, and their use is encouraged (**Figure 59-15**). Placement of these catheters is

FIGURE 83-9. The catheter-over-the-needle technique. **A.** The catheter-over-the-needle is inserted into the peritoneal cavity while maintaining negative pressure on the syringe. **B.** The needle and syringe are removed. **C.** A syringe is attached to the catheter. The aspiration of ascitic fluid confirms proper intraperitoneal placement of the catheter.

usually quick and simple. Consider using a Caldwell needle with fenestrations on the side to help minimize problems with the flow of fluid.

Choose the puncture site and prepare the patient for the procedure. Insert the catheter-over-the-needle through the skin in a Z-track manner and into the peritoneal cavity (**Figure 83-9A**). A flash of fluid in the hub of the needle confirms that the tip of the needle is within the peritoneal cavity. Advance the catheter-over-the-needle an additional 2 to 3 mm to ensure that the catheter is within the peritoneal cavity. Hold the hub of the needle securely. Advance the catheter over the needle until its hub is against the skin (**Figure 83-9B**). Withdraw the needle and syringe as a unit. Attach a syringe onto the hub of the catheter (**Figure 83-9C**). Aspirate fluid from the catheter to confirm intraperitoneal placement. Hold the hub of the catheter securely and remove the syringe. Pass the syringe to an assistant to place the sample into laboratory containers. Connect the catheter to intravenous tubing. Connect the other end of the tubing to a suction bottle or bag to drain the desired amount of fluid. An alternative is to attach a three-way stopcock to the distal end of the tubing.²² A syringe may then be attached to the stopcock to withdraw laboratory samples or “pump out” the ascitic fluid into a nonsterile container. Remove the catheter once the procedure is completed. Apply a bandage to the skin puncture site.

ULTRASOUND-ASSISTED AND -GUIDED PARACENTESIS

The use of US increases the success rates for performing a paracentesis and decreases complications.²⁷ US may be used to assist or guide the paracentesis. A static technique is used to identify the skin puncture site and ascitic fluid location. The remainder of the procedure is “blind” using one of the above described techniques. Place the US transducer back on the abdomen to locate the needle and determine if it is off target or not long enough to reach the peritoneal cavity if ascites is not aspirated.

A dynamic technique is used occasionally, and the needle is inserted using real-time US. Position the patient. Clean and prep the skin. Scan initially with a 3.5 to 5 MHz transducer longitudinally and transversely to survey each potential needle entry site (**Figure 83-10**).²³ Ascites appears anechoic (black) and outlines the loops of intestine (**Figure 83-11**). The intestine may be seen undulating in the ascites due to intestinal peristalsis. Without ascites, the individual loops of intestine cannot be visualized. Scan with the high-frequency 8 to 12 MHz transducer to provide improved resolution, improved identification of the inferior epigastric vessels, and better needle visualization during the procedure. Identify the inferior epigastric artery and vein in the abdominal wall (**Figure 83-12**).²⁸

FIGURE 83-10. The patient is positioned and being surveyed for the location of ascitic fluid.

FIGURE 83-11. The presence of anechoic free fluid (FF) allows the individual intestine loops to be discerned.

Note the amount of fluid and the presence of any structure that might make a site undesirable. Reposition the patient if no site seems suitable and repeat the US. Note the depth from the skin surface to the fluid. **Choose a site with the most fluid at the least depth.** Position the US transducer so that the target is in the middle of the US view screen. The entry site will now be under the center of the transducer. Mark the skin, wipe off the US gel, and repeat the prep. Prepare the US transducer. Have an assistant apply US gel over the footprint of the transducer. Instruct the assistant to place the gel-coated US transducer in the sterile cover while you hold it. Have the assistant place sterile US gel over the abdomen. Reidentify the ascites and proceed with the procedure (Figure 83-13).

Do not mistake a cystic fluid collection or the bladder for ascites. Ascites will outline individual intestine loops and appears in many places around the abdomen. Fluid in a cyst or the bladder has rounded borders and is localized. Loculated ascites will occasionally mimic a cyst but will still outline the loops of intestine.

FIGURE 83-12. Abdominal US image identifying the inferior epigastric vessels in the abdominal wall. The artery is red and the vein is blue. Hypoechoic ascites can be seen in the abdomen. (Used with permission from reference 28.)

FIGURE 83-13. The needle (arrows) is inserted through the abdominal wall and into the free fluid.

ALTERNATIVE TECHNIQUES

Use wall suction to safely and quickly remove a large volume of fluid (Figure 83-14).²⁹⁻³¹ The use of disposable plastic containers instead of bottles saves cost per patient.²⁹ This eliminates the need to find

FIGURE 83-14. Paracentesis set up using plastic vacuum containers mounted on a stand. The same set-up can stand on a bedside table. Note the paracentesis catheter (arrow) attached to the tubing. (Used with permission from reference 29.)

vacuum bottles, which are sometimes in short supply. There are many advantages to using plastic containers attached to wall suction (e.g., no shattering or exploding, no changing between bottles, and constant suction). Wall suction is often lower than the initial pressure in bottles and using a syringe attached to a stopcock.²⁹ The wall suction pressure can be adjusted where the bottles cannot be adjusted. The drainage is constant with wall suction because the pressure does not change. Bottle pressure decreases as the bottle fills with fluid, and the ascites comes out slower as the bottle becomes filled. Using plastic containers and wall suction may shorten the procedure time.

AFTERCARE

Bandage the skin puncture site once the procedure is completed. The site will occasionally ooze fluid in patients with tense ascites. Instruct these patients to change their dressings regularly. Occlusive tape can be helpful in preventing the fluid from leaking onto the patient's clothing and bedding. Sometimes a simple mattress or figure-of-eight suture is necessary to control the drainage. Emergency Physicians have used a tissue adhesive (e.g., Dermabond, Indermil, or Histoacryl) to help control a fluid leak.³² The patient may be discharged home if the purpose of the paracentesis was to relieve tense ascites, no signs or symptoms of SBP exist, and the fluid analysis is unremarkable. Instruct the patient verbally and in writing to immediately return to the Emergency Department if they develop abdominal distension, abdominal pain, fever, nausea, or vomiting.

The patient will require hospitalization and intravenous antibiotics if SBP is suspected or diagnosed. Administer empiric antibiotics that cover gram-negative enterics (of which *Escherichia coli* is the most likely) and streptococcal species (including *Enterococcus*) in the Emergency Department. A third-generation cephalosporin (e.g., cefotaxime) covers the most common causative agents.¹⁶ Add ampicillin if *Enterococcus* is suspected. Check previous culture results for antibiotic sensitivities if the patient has a history of SBP.

COMPLICATIONS

Complications from abdominal paracentesis are infrequent. Known complications include abdominal wall hematoma, intestine perforation, hemoperitoneum, infection, persistent ascitic fluid leak, shearing of the peritoneal catheter, and systemic hemodynamic compromise.

Bleeding is a potential complication of paracentesis.³³ The administration of prophylactic blood products (e.g., fresh frozen plasma) is not warranted.^{21,34,35} Spontaneous hemoperitoneum secondary to mesenteric variceal bleeding has been reported to occur in patients receiving large-volume (e.g., > 4000 mL) paracentesis.³⁶ Patients who developed this complication have had advanced cirrhosis with refractory ascites, hemorrhagic shock without evidence of gastrointestinal bleeding, and previous large-volume paracentesis. Mortality from this complication is exceedingly high. An additional vascular complication, an inferior epigastric artery pseudoaneurysm or injury, has been described.³⁷ Embolization may be warranted if there is large-volume hemorrhage.³⁸

Perforation of the intestine during paracentesis is rare. Most of these injuries are self-sealing and develop no further problems. Generalized peritonitis and abdominal wall abscesses have been reported and are exceedingly rare. Do not move the needle when it is within the peritoneal cavity to avoid lacerating the intestine wall.

Ascitic fluid may continue to leak from the site of paracentesis. Apply skin closure strips to the skin puncture site to stop leaks. This does not always work. A simple suture at the site may correct the problem. Evaluate patients with persistent leaks for peritonitis.

Rapid removal of significant amounts of ascitic fluid has been found to cause hemodynamic compromise.^{39,40} Initial removal of

TABLE 83-1 Laboratory Tests for Ascitic Fluid

Recommended	Optional	Unusual

Cell count	Glucose	Cytology
Cultures	Grams stain	Triglycerides
pH	Lactate dehydrogenase	
	Total protein	

large amounts of ascites causes improvement in circulatory function, likely related to both mechanical (e.g., improved cardiac venous return) and neurohumoral factors. Total paracentesis in cirrhotic patients may cause delayed (i.e., over 12 to 24 hours postprocedure) effective hypovolemia by accentuation of baseline arteriolar vasodilation through neurohumoral mechanisms.⁴¹ The literature suggests that some of the postparacentesis circulatory dysfunction may be avoided by pretreating patients with an intravenous colloid (e.g., albumin).^{19,39,42} This is not a universally accepted practice, and colloid replacement is likely unnecessary for patients with ≤ 5 L removed. A typical starting dose of albumin, if choosing to administer it, is 6 to 8 gm of albumin for every liter of ascites removed.^{19,43}

ASCITIC FLUID ANALYSIS

Normal ascitic fluid should appear clear with a yellow color. Increased turbidity may suggest infection, elevated triglyceride levels, or other particulate matter. Sanguineous fluid is present in patients with malignancy, intraperitoneal bleeding from the intraabdominal organs (i.e., iatrogenically or spontaneously introduced), or tuberculous peritonitis. The appearance of the ascitic fluid is not sensitive for detecting SBP and cannot be used as a screening tool.⁴⁴⁻⁴⁷

The specific analytical tests ordered on ascitic fluid should reflect the Emergency Physician's clinical suspicion (**Table 83-1**). Simple analysis of fluid with an albumin concentration, cell count and differential, and routine cultures are all that is necessary in patients with uncomplicated cirrhosis. These initial tests can be supplemented depending on clinical suspicion. An ascitic fluid pH < 7.35 and a blood-ascitic fluid pH gradient ≥ 0.10 can aid in the diagnosis of SBP.⁸ Amylase, bilirubin, glucose, lactate dehydrogenase, total protein, and triglycerides are not helpful except in select circumstances and are not warranted on a routine basis. The serum-ascites albumin gradient is approximately 97% accurate in indicating portal hypertension.^{6,48} The gradient is calculated by subtracting the ascitic fluid albumin concentration from the simultaneously measured serum albumin concentration. A gradient of ≥ 1.1 gm/dL suggests portal hypertension as the etiology of the ascites (**Table 83-2**). A gradient of < 1.1 gm/dL suggests that the patient does not have

TABLE 83-2 Classification of Ascites by the Serum to Ascites Albumin Concentration Gradient

High gradient (≥ 1.1 gm/dL)	Low gradient (< 1.1 gm/dL)
Alcoholic hepatitis	Nephrotic syndrome

Massive liver metastases	
Mixed ascites	
Myxedema	
Portal vein thrombosis	
Venoocclusive disease	

portal hypertension and that the ascites has some other etiology (Table 83-2). A dipstick for glucose, pH, and protein can be used to differentiate an exudate from a transudate.⁴⁹ This method uses a hard to remember equation and requires the use of a calculator ($k = 0.012\text{protein} - 0.012\text{glucose} - 3.329\text{pH} + 23.498$).

Suspect peritoneal carcinomatosis and order cytology in patients with a history of breast cancer, colon cancer, gastric cancer, pancreatic cancer, or the suspicion of undiagnosed malignancy and ascites. Smear and cultures for mycobacteria are not sensitive. They should still be ordered when the suspicion for tuberculous peritonitis is high (e.g., patients who have immigrated from endemic areas or have an immunocompromised status).⁵⁰

Patients with uncomplicated ascites secondary to cirrhosis should have an ascitic fluid white blood cell (WBC) count < 500 cells/mm³. The cells should be predominantly lymphocytes and mesothelial cells without clinical evidence of peritonitis. A polymorphonuclear (PMN) cell or neutrophil count of > 250 cells/mm³ confirms SBP.⁵¹ The PMN count is obtained by multiplying the total WBC count by the percentage of PMNs in the differential. Subtract one neutrophil per 250 red cells/mm³ to adjust for significant blood in a specimen (i.e., RBC $> 10,000$ cells/mm³) from a traumatic tap.¹⁶ A Gram stain is not sensitive for SBP secondary to the low concentration of bacteria in ascites. Patients receiving continuous peritoneal dialysis can have SBP diagnosed with a WBC > 100 cells/mm³.⁵¹ **Culture all potentially infected ascitic fluid by directly inoculating blood culture bottles at the bedside.**^{25,26}

SUMMARY

Paracentesis is a safe procedure that is common in the practice of Emergency Medicine. There are few relative contraindications to its performance. It is most commonly performed diagnostically to detect SBP. It can be performed therapeutically for symptomatic relief in patients with tense ascites. Proper technique with assistance of US can increase the chances of a successful paracentesis while decreasing the chances of complications.

Diagnostic Peritoneal Lavage

Leann Mainis and Rene Ramirez

INTRODUCTION

The diagnostic peritoneal lavage (DPL) was first described in 1965 by Dr. Root who developed a method for sampling the peritoneal cavity to more rapidly determine the presence of hemoperitoneum after trauma.¹ The initial physical examination can be misleading in up to 45% of blunt trauma patients, and DPL can be useful in diagnosing intraabdominal injury in a timely fashion.²⁻⁴ DPL is performed less frequently due to the use of focused abdominal sonography for trauma (FAST) bedside ultrasound (US) scanning and helical computed tomography (CT).^{5,6} DPL is the only invasive test of the three and remains a highly sensitive test for mesenteric and hollow viscus injuries.^{4,7,8} The main disadvantages of DPL are that it gives no information about the specific organ injured and a positive DPL requires an invasive procedure in the Operating Room versus conservative management and observation. The overall use of DPL is declining with the progression of advanced CT scanning, repeat/serial FAST exams, and the increased availability of these modalities.^{3,5,9}

Dr. Root's description of the DPL represented an improvement upon the use of paracentesis to identify a hemoperitoneum as described by Salomon in 1906.¹⁰ His initial description of a DPL used a trocar placed into the peritoneal cavity to instill fluid. The fluid was visually inspected upon removal and the patient then underwent a laparotomy if it appeared bloody.

DPL has undergone several modifications since its initial description. The trocar technique was initially abandoned in favor of the open technique, which later fell to the Seldinger or closed technique.^{11,12} A novel method that combines the use of diagnostic laparoscopy and DPL has been termed laparoscopic diagnostic peritoneal lavage (L-DPL).¹³ This procedure combines the visual advantages of laparoscopy with the sensitivity and specificity of a DPL for the diagnosis of significant penetrating intraabdominal injury.

While the DPL was first described for blunt abdominal trauma, it has found an indication in the patient with penetrating abdominal trauma.² Initial attempts to quantify the effluent based on its appearance have been replaced by the red blood cell (RBC) count, the white blood cell (WBC) count, and the measurement of various enzymes.¹⁴⁻¹⁶ The debate is still present in the literature as to which criterion best determines the need for a laparotomy.

ANATOMY AND PATHOPHYSIOLOGY

The gross anatomy of the abdomen is well known to the Emergency Physician and is important to review when preparing for a DPL. The abdominal cavity is lined by the peritoneum and is protected from the environment by the abdominal wall musculature, fat, and skin. The right and left rectus muscles, which are nourished by the epigastric vessels, meet in the midline at the avascular linea alba. The umbilicus is located along the lower portion of the linea alba. The layers of the anterior abdominal wall structures vary above and below the level of the anterior superior iliac spine (**Figure 84-1**).

The DPL is always performed in the anterior midline of the abdomen (Figure 84-2). The linea alba is an avascular location through which the peritoneal cavity may be entered using either an open technique or a closed Seldinger type technique. This midline location minimizes the number of false-positive lavages that occur due to bleeding from the abdominal wall muscles or blood vessels. This also allows the Surgeon to perform a midline laparotomy, if necessary, through the lavage site and avoid the formation of an avascular skin bridge.

Most DPLs may be safely performed 1 to 2 cm below the umbilicus (**Figures 84-2A and 84-2B**). This location allows the DPL catheter to be directed into the pelvis, minimizes the occurrence of inadvertent vascular injury, and increases the likelihood that fluid will be sampled from a dependent portion of the abdomen. It is more difficult to retrieve fluid if the DPL is performed above the umbilicus due to interference from the omentum. All closed and semi-open DPLs, as well as many open DPLs, are performed below the umbilicus.

The resultant retroperitoneal hematoma in patients with a pelvic fracture may extend anteriorly to the level of the linea semilunaris. **Perform the DPL in patients with a pelvic fracture using an open technique above the umbilicus (Figure 84-2C).** This will avoid a false-positive DPL and the inadvertent decompression of the hematoma.¹⁷

Another special situation occurs in the pregnant patient. **Perform the DPL using an open technique superior to the uterine fundus to minimize the chance of injuring the gravid uterus.**¹¹ It may be performed below the umbilicus if the patient is in an early stage of pregnancy.

It may be necessary to change the location of the DPL site in a patient with previous abdominal surgery. These patients must be individualized based on the location of their scar. The DPL should be performed supraumbilically if the patient has a lower abdominal scar and infraumbilically if the patient has an upper abdominal scar.^{11,14} **Perform the DPL using an open technique to avoid any adhesions and minimize complications.**¹⁸

INDICATIONS

A DPL is indicated in any patient with suspected abdominal trauma, blunt or penetrating, who does not have an obvious indication for a laparotomy and in whom serial physical examinations are not practical. It can be performed quickly, will reliably exclude significant intraabdominal trauma, and will allow the diagnosis and treatment of associated injuries. It does not require transfer of the patient out of the monitored environment of the Emergency Department as does a CT scan. DPL does not require the sophisticated equipment or US training that is required to perform a FAST exam.

FIGURE 84-1. The layers of the anterior abdominal wall vary above (A) and below (B) the level of the anterior superior iliac spine.

A DPL is especially useful in patients with an unreliable or equivocal abdominal examination and those who will be unavailable for serial physical examinations. The patient with an altered mental status (e.g., alcohol, drugs, head injury) or abnormal sensation due to a spinal cord injury is considered to have an unreliable physical examination.^{11,16,19} Patients may have an equivocal examination due to tenderness from surrounding fractures of the ribs, spine, or pelvis.^{16,18} They may have tenderness over the wound or an area of injury that is difficult to distinguish from peritonitis. The third group of patients who may benefit are those who undergo surgery for another injury (e.g., neurosurgical or orthopedic).¹⁹ These patients are unavailable for serial examinations while in the Operating Room. Their examination may be altered postoperatively due to the analgesics that they receive.

DPL may be useful when the patient presents in shock with other potential sources of hemorrhage (e.g., intrathoracic or retroperitoneal bleeding). It may confirm or rule out the abdomen as the source of the patient's bleeding and shock.¹¹ **An injury confined to the retroperitoneum will not result in a positive DPL.**²⁰ DPL can be used in critically ill patients with possible mesenteric ischemia and decrease operative procedures.²¹ A DPL has been used to stage gastric cancer.²²

CONTRAINDICATIONS

The only absolute contraindication to performing a DPL is if the patient has an obvious indication for a laparotomy. Patients who present following abdominal trauma with blood per orifice, evisceration, peritonitis, pneumoperitoneum on chest radiography, retained stabbing implements, or shock have obvious indications for

a laparotomy. Preexisting coagulopathy is a relative contraindication due to increased risk of bleeding.

There are several relative contraindications to performing a closed DPL. Patients with a pelvic fracture may have a large retroperitoneal hematoma that extends anteriorly to the linea semilunares. The DPL may be performed using the open technique above the umbilicus to avoid decompression of the hematoma.¹⁷ Pregnant patients should not have a closed DPL performed because of the risk of uterine injury. It is safe to perform an open DPL above the uterine fundus.¹¹ Patients with evidence of previous abdominal surgery may have visceral adhesions to the abdominal wall that make intraabdominal injury more likely to result when a closed DPL is performed.^{1,14} An open technique may be performed in a location away from the scar.¹⁸ Compartmentalization of the abdomen may have occurred due to intraperitoneal adhesions. This makes a false-negative DPL result more likely. Perform the DPL using the open technique in patients who are unable to have a Foley catheter placed due to urethral injury or stricture. This minimizes the chance of inadvertent injury to the bladder. Morbid obesity represents a difficulty in technically performing the DPL when the abdominal wall is thicker than the 2.5 inch long locator needle. It is useful to perform the DPL in these patients using a semi-open technique.²³

EQUIPMENT

CLOSED TECHNIQUE

- Povidone iodine or chlorhexidine solution
- Face mask
- Sterile gloves

FIGURE 84-2. The preferred sites to perform a DPL. **A.** The midline and approximately 1 to 2 cm below the umbilicus is the location for a closed DPL. **B.** A midline incision beginning 1 to 2 cm below the umbilicus and extending inferiorly for 5 to 6 cm is the location for semi-open and select open DPLs. **C.** A midline incision beginning 2 cm above the umbilicus and extending superiorly for 5 to 6 cm is the location for most open DPLs.

- Sterile gown
- 4×4 gauze squares
- Local anesthetic solution
- Purple top blood collection tube
- 5 mL syringes
- 18 gauge needles
- 25 gauge needles
- Nasogastric tube
- Foley catheter
- 1 L of intravenous fluid to infuse 0.9% NaCl or lactated Ringer's solution
- Commercial peritoneal lavage kit (e.g., Arrow AK-09000)

SEMI-OPEN OR OPEN TECHNIQUE

- All items listed above
- Razor
- #10 scalpel blade on a handle
- Abdominal skin retractors, Weitlaner or skin rakes
- 2 tissue forceps
- 2 Allis clamps
- 4 hemostats
- Needle driver
- Suture for vessel ligation (e.g., 4-0 Vicryl, 4-0 Dexon, or 4-0 chromic)

FIGURE 84-3. The equipment required to perform a closed DPL. Note that lavage fluid is not included.

- Suture for fascial closure (e.g., 0 Vicryl, 0 Dexon, 0 Maxon, or 0 Prolene)
- 4-0 nylon suture or skin stapler for skin closure
- Suture scissors

A commercially available, disposable, and single-patient use peritoneal lavage kit is available from numerous manufacturers. The kit includes all the material required to perform a closed DPL except lavage fluid and the personal protective equipment for the Emergency Physician (**Figure 84-3**). An example is the Arrow kit (Arrow International, Reading, PA). It contains 10% povidone iodine swabs, gauze squares, a fenestrated drape, intravenous (IV) fluid administration tubing, 1% lidocaine, 5 mL syringes, 22 and 25 gauge needles, an 18 gauge × 2.5 inch introducer needle, an 0.89 mm × 45 cm J-tipped guidewire, a lavage catheter, and a #11 blade scalpel.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. This should include the possible complications and alternative options (e.g., observation or serial FAST exams). Obtain an informed consent from the patient or from the family if the patient is unable to consent due to age or mental status. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. **The consent process should not delay the performance of the DPL in an unstable patient.**

Place the patient in the supine position. A distended stomach or bladder may be inadvertently perforated during the procedure and require decompression prior to performing a DPL (**Figure 84-4**). Decompress the stomach using a nasogastric or orogastric tube (Chapter 75).^{19,24} Decompress the bladder using a Foley catheter once a urethral injury has been ruled out (Chapters 173 and 176).^{11,12,19,24}

FIGURE 84-4. Midsagittal section through the abdomen and pelvis demonstrating decompression of the stomach with a nasogastric tube and decompression of the bladder with a Foley catheter.

Prepare the abdomen.¹⁹ Shave the area surrounding the incision site if an open or semi-open DPL is to be performed. Clean the skin of any dirt, debris, and blood. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to delineate a sterile field. Each health care provider involved in the procedure should don a hat, face mask, sterile gown, and sterile gloves.¹⁹

TECHNIQUES

A DPL is performed one of three different ways: closed, open, or semi-open.^{25,26} The closed technique relies on percutaneous needle access to the peritoneal cavity followed by the insertion of a catheter using the Seldinger technique. The open technique uses a vertical infraumbilical incision and direct visualization of the peritoneal cavity before inserting the catheter. The semi-open technique follows the same principles of the open technique except that the midline fascia is penetrated with a needle and the catheter is advanced using the Seldinger technique. There is no difference in overall outcomes or rates of injury to visceral contents between the three techniques.²⁷⁻³⁰

PERCUTANEOUS (CLOSED) TECHNIQUE

The closed technique is the preferred method unless contraindications exist (Figure 84-5). The closed DPL can be performed more rapidly than the open technique.^{27,30} There is no difference in the amount of fluid retrieved from the abdomen, the diagnostic accuracy, or the complication rate between the closed and open techniques.²⁷

The closed DPL is performed in the midline and approximately 1 to 2 cm below the umbilicus (Figure 84-2A).²⁴ Prepare the patient as described previously. Infiltrate the skin, subcutaneous tissue, and fascia with local anesthetic solution. Place the 2.5 inch introducer needle onto a 5 mL syringe. Insert the needle in the midline and 1 to 2 cm below the umbilicus. Advance the needle at a 45° angle toward the pelvis (Figure 84-5A). Apply negative pressure to the syringe as it is advanced. Three “pops” may be felt as the needle penetrates the skin, fascia, and peritoneum. Slowly advance the needle after the third pop another 2 to 3 mm while maintaining negative pressure on the syringe. **A flash of blood will be seen in the syringe if the patient has a massive hemoperitoneum. This is considered a positive tap and concludes the procedure.**

Continue the procedure if the tap is negative. Stabilize the introducer needle with one hand at the level of the abdominal wall and

remove the syringe. **Do not allow the introducer needle to move as it may lacerate the intraabdominal organs.** Insert the guidewire through the introducer needle until 7 to 10 cm of the guidewire remains outside of the hub of the needle (Figure 84-5B). The guidewire should advance through the needle easily with only minimal resistance. **Difficulty in advancing the guidewire or the patient complaining of pain requires removal of the guidewire and introducer needle as a unit. Never withdraw the guidewire through the introducer needle.** The tip of the introducer needle can shear off the guidewire resulting in a piece of the guidewire being left in the peritoneal cavity and necessitating an operative procedure. Reinsert the introducer needle and restart the procedure.

Stabilize the guidewire and withdraw the introducer needle over the guidewire (Figure 84-5C). Make a small incision in the skin and subcutaneous tissue alongside the guidewire with a #11 scalpel blade to facilitate passage of the lavage catheter (Figure 84-5D). **Make the incision no more than 5 mm in length.**

Place the lavage catheter over the guidewire (Figure 84-5E). Advance the lavage catheter into the peritoneal cavity (Figure 84-5F). It may be helpful to gently twist the catheter as it passes through the fascia to aid in inserting it into the peritoneal cavity. Advance the catheter until its hub is against the abdominal wall in the adult patient. Securely hold the hub of the lavage catheter. Remove the guidewire (Figure 84-5G). Attach a 5 to 10 mL syringe to the hub of the lavage catheter. Apply negative pressure to the syringe. Note if any blood is aspirated. **The aspiration of a small amount of blood is not considered to be a positive tap and the procedure should continue.**

The presence of gross blood upon entering the peritoneal cavity with the introducer needle (i.e., positive tap) is considered an indication for laparotomy. It represents blood throughout the peritoneum. Confusion exists when blood is withdrawn through the lavage catheter (i.e., peritoneal aspirate). It is considered a positive aspirate and concludes the procedure if 10 mL of blood, gross bile, stool, or food is aspirated initially by the lavage catheter.³¹ The patient should be prepped for a laparotomy. The DPL catheter has been directed into the most dependent portion of the peritoneal cavity (Figure 84-6). **A small amount of blood withdrawn (i.e., less than 10 mL) through the catheter may represent the only blood present within the abdomen and is not an indication for laparotomy.**¹⁹

Continue the procedure if the aspirate is negative. Pass the proximal end of the IV tubing to a nonsterile assistant to insert into a bag of IV fluid (e.g., 0.9% NaCl or Ringer’s lactate) and prime the tubing. Warmed IV fluid is preferable to room temperature fluid if available. Attach the distal end of the IV tubing to the lavage catheter (Figure 84-7A). Open the clamp on the IV tubing and allow the lavage fluid to flow freely into the peritoneal cavity (Figure 84-7A). The lavage catheter may not be within the peritoneal cavity if the lavage fluid does not flow quickly but seems to drip in slowly. Reassess the catheter position. If necessary, remove and reinsert the lavage catheter. Infuse 1 L in the adult patient and 10 to 20 mL/kg to a maximum of 1 L in the pediatric patient.^{12,18} Stabilize the catheter with one hand during the infusion of the lavage fluid.

Place the fluid bag on the floor after the lavage fluid has been instilled to allow the fluid to flow out from the peritoneal cavity (Figure 84-7B). **There should be a steady rate of flow of the lavage fluid from the patient’s abdomen into the bag.** Diminution of flow usually results from the omentum blocking the side holes of the lavage catheter. Firm palpation of the patient’s abdomen may increase the flow rate if it slows. The lavage catheter may need to be withdrawn slightly and reinserted. These maneuvers may help to dislodge the omentum. If manipulation of the catheter does not improve flow, a second liter of fluid may be infused in an adult and an additional 10 mL/kg in children. The threshold for a positive

FIGURE 84-5. The percutaneous or closed DPL technique. **A.** The introducer needle is advanced caudally and at a 45° angle to the skin of the abdominal wall while negative pressure is applied to the syringe. **B.** The syringe has been removed and the guidewire is inserted through the introducer needle. **C.** The introducer needle is withdrawn over the guidewire, leaving the guidewire in place. **D.** A small nick is made in the skin and subcutaneous tissue adjacent to the guidewire using a #11 scalpel blade. **E.** The lavage catheter is placed over the guidewire. **F.** The lavage catheter is advanced over the guidewire and into the peritoneal cavity. A twisting motion may aid in the advancement of the catheter. **G.** The guidewire is removed, leaving the lavage catheter in place.

DPL must be halved (i.e., down from 100,000 to 50,000 RBC/mm³ in blunt trauma) if it becomes necessary to infuse additional fluid as twice the fluid is infused diluting the RBC concentration.

At least 300 to 350 mL of lavage fluid should be returned from the peritoneal cavity to result in a reliable cell count.^{9,30,32,33} This fluid is referred to as the effluent. Place a new lavage catheter if less than 300

to 350 mL of effluent is obtained after the manipulations described above.^{9,12} Remove the existing lavage catheter while maintaining the sterility of the distal end of the IV tubing. Place a second lavage catheter 1 cm inferior to the site of the first lavage catheter. Reconnect the IV tubing and place the IV bag to gravity drainage to obtain the lavage effluent.

FIGURE 84-6. Midsagittal view of the body cavities. (Modified from <http://en.wikipedia.org/wiki/laparotomy>.)

Remove the lavage catheter after obtaining as much effluent as possible from the peritoneal cavity. Place a small gauze dressing over the skin puncture site and remove the drapes. Transfer a small aliquot of the lavage effluent to a purple top blood collection tube. Transport the tube to the laboratory for a cell count. The remainder of the lavage effluent may be discarded or reserved for subsequent testing.

OPEN TECHNIQUE

Prepare the patient as described previously. Infiltrate the skin, subcutaneous tissue, and fascia with a local anesthetic solution in the area where the incision is to be made. Begin the incision 2 cm below the umbilicus and extend it 5 to 6 cm inferiorly in patients who have an upper abdominal scar (**Figure 84-2B**). Begin the incision 2 cm above the umbilicus and extend it 5 to 6 cm superiorly in patients with a pelvic fracture or lower abdominal scar (**Figure 84-2C**). Make the incision in the midline above the uterine fundus in patients who are pregnant.

Incise the skin and subcutaneous tissue longitudinally 5 to 6 cm in the midline (**Figure 84-8A**). The incision may need to be longer in an obese patient. Clamp and ligate any small vessels that are bleeding with absorbable suture prior to incising the fascia. This will minimize the incidence of false-positive lavage results. Retract the skin and subcutaneous tissues with a Weitlaner retractor or skin rakes to aid in viewing the fascia (**Figure 84-8B**). The fascial midline may be identified by the interdigitation of its fibers (**Figure 84-8B**). Carefully incise the fascia longitudinally along the length of the previous skin incision (**Figure 84-8C**). Identify the peritoneum. Any preperitoneal fat that is present can be gently moved aside by an assistant using either a forceps or gauze. Grasp and elevate the peritoneum using two Allis clamps (**Figure 84-8D**). **Use extreme care to ensure that no bowel is included in the clamps.**

Make a small (i.e., <5 mm) incision in the peritoneum. Insert the lavage catheter through the incision and directed caudally into the pelvis (**Figure 84-8E**).¹¹ The remainder of the procedure is as described above in the percutaneous (i.e., closed) technique. It may be necessary to gently retract the peritoneum upward with the Allis clamps to prevent leakage of the lavage fluid around the catheter.

FIGURE 84-7. The instillation and removal of lavage fluid. **A.** The fluid bag is attached to the lavage catheter using IV tubing. The fluid bag is then suspended and allowed to infuse into the peritoneal cavity. **B.** The fluid bag is placed on the floor to allow the lavage fluid to exit the peritoneal cavity and flow back into the bag.

Remove the lavage catheter and Allis clamps after obtaining as much effluent as possible from the peritoneal cavity. It is not necessary to suture the peritoneum. Close the fascia with #0 Maxon, Prolene, Vicryl, or Dexon suture in a running fashion. Inspect the edges of the incision for any bleeding blood vessels. Obtain hemostasis of the subcutaneous tissue by ligating small vessels with absorbable suture. Close the skin with interrupted 4-0 nylon sutures or skin staples. Place a gauze dressing over the incision site. Remove the drapes.

SEMI-OPEN TECHNIQUE

This technique is used primarily for patients in whom there is no contraindication to the performance of a closed lavage and their abdominal wall is thicker (e.g., > 2.5 inches) than the length of the introducer needle. The procedure often begins as a closed technique and is converted to a semi-open technique once it is realized that the introducer needle is not long enough to enter the peritoneal cavity. It is a modification of both the closed and open techniques.²³

Prepare the patient and begin the procedure as if performing the open technique. Make the midline incision and retract the tissues (**Figures 84-8A and 84-8B**). Identify the interdigitations

of the fascia in the midline. Place the introducer needle on a 5 mL syringe. Insert the introducer needle through the midline and at a 45° angle directed toward the pelvis (**Figure 84-5A**). Apply negative pressure to the syringe while advancing the needle. A pop will be felt as the introducer needle penetrates the peritoneum. The remainder of the procedure is as described above under the percutaneous or closed technique.

Remove the lavage catheter after obtaining as much lavage fluid as possible from the peritoneal cavity. Inspect the edges of the incision for any bleeding blood vessels. Obtain hemostasis of the subcutaneous tissue by ligating small vessels with absorbable suture. Close the skin using interrupted 4-0 nylon sutures or skin staples. Place a gauze dressing over the skin incision site. Remove the drapes.

FIGURE 84-8. The open DPL. **A.** An incision is made in the skin and subcutaneous tissues. **B.** The skin and subcutaneous tissues are retracted. Note the interdigitation of the fibers of the fascia in the midline. **C.** An incision is made in the fascia. **D.** The peritoneum is grasped and elevated with Allis clamps. **E.** The lavage catheter is inserted through a small incision in the peritoneum.

LAPAROSCOPIC DPL (L-DPL)

The technique of L-DPL should be considered in hemodynamically stable patients with penetrating lower thoracic or abdominal stab wounds.¹³ It is especially applicable for Trauma Surgeons with experience in basic laparoscopic techniques. The procedure is used to obtain conclusive evidence of significant intraabdominal injury, confirm peritoneal penetration, control intraabdominal bleeding, and repair lacerations (e.g., diaphragm and abdominal wall). The combination of laparoscopy and DPL adds to the sensitivity and specificity of DPL and avoids under- or oversensitivity, which has limited the use of DPL in hemodynamically stable trauma patients with suspicious or proven peritoneal penetration.

ANALYSIS OF PERITONEAL LAVAGE FLUID

There are several laboratory evaluations that can be performed on the lavage effluent to determine whether the patient requires a laparotomy. Gross evidence of injury exists when there is a positive peritoneal tap or aspirate, bile-stained peritoneal fluid is seen in the effluent, or enteric contents are seen in the effluent.^{14,25} The most commonly used laboratory determination is that of the erythrocyte or RBC count. Other determinations include the leukocyte count and the presence of amylase in the lavage effluent.

Peritoneal lavage was first described as using visual inspection of fluid for the presence of blood.^{1,7,14} This has been subsequently shown to be very inaccurate, even when performed by experienced physicians.³⁴ A much better method of quantification of the presence of blood uses the counting of erythrocytes manually or with an automated cell counter.

A positive DPL in an adult classically requires one of the following results: blood on the initial tap, 10 mL of gross blood on aspiration, greater than 500/mm³ WBCs, greater than 100,000/mm³ RBCs, or the presence of enteric contents or food matter.⁹ The RBC count threshold can be adjusted from 100,000 RBC/mm³ in patients who have sustained blunt trauma or an anterior abdominal stab wound to a lower count of 10,000 RBC/mm³ in patients who may have suffered penetration of the abdominal cavity. Both counts appear to be very sensitive, specific, and accurate at diagnosing injury or penetration.³⁵

In blunt abdominal trauma, 100,000 RBCs/mm³ is the most commonly used threshold for a laparotomy.^{11,16,25} This corresponds roughly to the presence of 20 mL of blood in the peritoneal cavity. Using the count of 100,000 RBCs/mm³ to determine the presence of a hemoperitoneum provides a sensitivity of 77% to 97% and a specificity of 93% to 99.6%.^{9,16} The false-positive results that occur are usually the result of bleeding from the lavage site. False-negative DPLs usually result in red blood cell counts in the mid-10,000s, which some authors refer to as indeterminate.¹¹ The injuries that are missed by a count of 100,000 RBCs/mm³ are injuries to hollow viscera and the diaphragm, organs that may not bleed enough to result in a positive lavage.

Penetrating trauma has no universally agreed upon threshold for a laparotomy. Penetration of the peritoneal cavity is felt to be an indication for laparotomy in all gunshot wounds and most stab wounds to the abdomen. Peritoneal penetration by a gunshot wound results in a significant intraperitoneal injury in 98% of cases.³⁶ DPL to prove abdominal penetration is useful in cases of potentially tangential gunshot wounds.^{20,37} Penetration into the peritoneal cavity from a thoracoabdominal wound results in a diaphragmatic injury that should be repaired.^{24,38} Penetration through the retroperitoneum, from the back or flank, will cause a significant injury in 73% of cases.^{20,32} Penetration of the peritoneal cavity may not bleed enough to result in a 100,000 RBCs/mm³ count. Most authors believe that a lower RBC count should be used.

The RBC count varies from 1,000 to 50,000 RBCs/mm³ as a threshold for laparotomy in penetrating trauma.^{16,23,30,38-40} Higher cell counts are more likely to result in a greater false-negative rate.^{16,19,24} Lower cell counts are more likely to result in a negative laparotomy and an increased false-positive rate.^{16,17,24} A threshold of 10,000 to 25,000 RBCs/mm³ provides the most acceptable balance between false-negative and false-positive results.^{24,37,39,41} This threshold results in a sensitivity of 88% to 99%, a specificity of 97% to 98%, and an accuracy of 95% to 98%.^{19,24,37}

A special case of penetrating abdominal trauma exists when there is a stab wound to the anterior abdomen. Only two-thirds of these wounds will penetrate the peritoneum. Less than 50% of those that penetrate will cause an injury that requires repair.²⁰ Using a lower threshold for DPL to determine penetration will result in a greater than 50% negative laparotomy rate. Wounds to the anterior abdomen are lavaged with the standard RBC count of 100,000 RBCs/mm³ to determine injury, and not penetration, as the threshold for an operation.⁴²

Many laboratories will routinely report the WBC count on the lavage effluent. The presence of over 500 WBCs/mm³ is often quoted as a standard indication for a laparotomy.²⁵ The presence of an elevated lavage WBC count by itself has poor predictive value in the trauma patient.³² There is commonly an associated elevation in the RBC count that will trigger a laparotomy. A recently described "cell count ratio" may help to diagnose the presence of a hollow viscus injury by comparing the WBC/RBC ratio in the lavage effluent to the WBC/RBC ratio in the blood.^{43,44} There is a high likelihood of hollow viscus injury if the lavage ratio is greater than that of blood. This ratio is not universally accepted.

While the quantification of RBCs and occasionally WBCs in the DPL effluent is the most common test, other laboratory tests may be used in indeterminate cases. The most commonly used is the determination of amylase.^{2,11,14} Amylase may be elevated in the presence of an injury to the gastrointestinal tract. The amylase level is neither sensitive nor specific.¹⁵

AFTERCARE

Observe the patient for up to 24 hours after performance of a negative DPL. The Foley catheter and nasogastric tube may be removed if they are no longer needed for other indications. Reexamine the patient periodically during this observation period for the development of peritonitis that may result from a false-negative lavage or a complication of the lavage procedure. The performance of the lavage should not alter the patient's examination, although there may be localized wound tenderness if the lavage was performed using the open or semi-open technique.¹ Prescribe analgesics as needed after the procedure. Keep the patient NPO during the initial portion of their observation. They can be fed near the end of the 24 hours to verify they tolerate oral intake prior to discharge.

Discharge instructions for the patient should instruct them to return for the development of a fever, nausea, vomiting, increasing abdominal or wound pain, or wound drainage. The patient should be seen in 7 to 10 days for removal of the skin sutures or staples after undergoing an open or semi-open DPL. No evidence exists supporting the use of prophylactic antibiotics.

COMPLICATIONS

The complication rate for DPL is relatively low. It varies between 0.6% to 2.3%.^{18,45} There is no difference in complication rates between the three techniques.²⁷⁻³⁰ The complications may be classified as wound-related or puncture-related.

Wound-related complications occur primarily with open or semi-open lavage techniques. Inadequate hemostasis during performance

of the DPL may result in bleeding and a hematoma formation at the wound site.^{11,18,45} There is a risk of wound infection at the lavage site.¹¹ This infection is usually due to skin flora and may be treated simply by opening the wound and performing twice-daily wet-to-dry dressing changes.

Puncture-related complications may occur after any DPL technique. Virtually any organ within the abdominal cavity may be punctured by the introducer needle, the guidewire, or the lavage catheter. Puncture of the bladder and stomach may be avoided by placing a Foley catheter and nasogastric tube, respectively, prior to performing the DPL.^{19,24} A punctured bladder is usually noted by obtaining urine during syringe aspiration or by lavage fluid exiting through the Foley catheter. Removing the lavage catheter and continuing Foley catheter drainage for 24 to 48 hours will treat this complication.¹⁴ Puncture of the small bowel, colon, and their mesenteries may occur.^{11,18,19,41,45} Puncture of blood vessels (e.g., ranging from mesenteric vessels to iliac vessels) has been described.¹ These latter complications will usually result in a positive DPL based on bleeding or return of enteric contents and are repaired at laparotomy.

Some advocate using the abdominal wound to insert the lavage catheter and not making a fresh entry site.⁴⁶ **This is not recommended.** This can result in false-positive results from blood in the wound tract, it can increase the potential for infection, the wound may be too far away that the catheter cannot reach into the pelvic recesses, and the lavage catheter could track through injured organs.

The lavage fluid may be instilled into the abdominal wall or the retroperitoneum on occasion.^{1,19} This may result in a false-positive lavage, a false-negative lavage, or more commonly an inadequate lavage fluid return. This complication requires no specific treatment other than recognition. The body will reabsorb the fluid over time.

SUMMARY

The diagnostic peritoneal lavage is a well-described procedure for determining the need for a laparotomy after trauma. It has undergone several modifications since its initial description over 50 years ago. The procedure may be performed using a closed, semi-open, or open technique depending on the patient's history and associated injuries. All three techniques are safe, accurate, and easily performed. Several criteria may indicate a positive result, and knowledge of these criteria is important in the evaluation of the DPL effluent.

It is important that a DPL be performed after informed consent (if feasible) and using strict sterile technique because this is an invasive procedure. There is a small risk of complications and missed injuries necessitating the close observation of the patient with a negative DPL.

The DPL remains one of the most useful tests in the patient with abdominal trauma.²⁶ The DPL remains the test of choice in the patient with penetrating abdominal trauma and in select patients with blunt abdominal trauma despite advances in imaging technology.

Anal Fissure Management

Eric F. Reichman

INTRODUCTION

An anal fissure, or fissure-in-ano, is one of the most common anal disorders seen by physicians. It is a linear tear or crack that extends into the anoderm from the mucocutaneous junction to the dentate line (**Figure 85-1**). An anal fissure usually results from the passage of hard stool that traumatizes and tears the anoderm. Frequent bowel movements with diarrhea can cause similar “cracks” that eventually result in fissures. Anal fissures are often seen in infants but primarily are a condition of young and middle-aged adults.¹⁻³ It is the most common cause of acute-onset painful rectal bleeding in adults and in the first year of life. Thus, some form of “trauma” results in anal sphincter spasm that causes ischemia.^{4,5}

A fissure may be acute or chronic, occur at any age, and affect both genders equally. It is the most common cause of rectal bleeding in infants. Fissures are typically a few millimeters long and occur primarily (85% to 90%) in the posterior midline.⁵ The remaining 10% to 15% are found in the anterior area.⁵⁻⁸ There is a slight gender difference, with 1% to 7% of anal fissures found anteriorly in men and up to 12% anteriorly in women.⁹ Atypical locations (e.g., lateral) account for 1% and suggest the presence of an underlying disease such as anal cancer, Crohn's disease, HIV, leukemia, previous anal surgery, syphilis, tuberculosis, and other infections.^{5,10}

ANATOMY AND PATHOPHYSIOLOGY

The anal canal begins at the level of the anorectal ring and extends distally for 4 cm to the anal verge. The internal anal sphincter and external anal sphincter muscles surround the anal canal. The internal anal sphincter muscle is a continuation of the involuntary layer of circular smooth muscle of the rectum that begins at the anorectal ring. It is approximately 2.5 to 4.0 cm long and 2 to 3 mm thick. The internal anal sphincter is not under voluntary control and is continuously contracted to prevent unplanned stooling. It is contracted at rest so that the lower margin can be palpated 1 to 2 cm below the dentate line in the intersphincteric groove. The internal anal sphincter muscle supplies up to 60% of the resting tone of the anus.¹¹ The external anal sphincter muscle is an elliptical cylinder of voluntary striated muscle tethered to the coccyx and surrounding the anal canal. It merges proximally with the puborectalis and levator ani muscle. It is voluntarily controlled. Columnar epithelium lines the upper anal canal while the lower anal canal is lined by squamous epithelium. The transitional zone lies between the two different types of mucosa. The anoderm is a thin layer of stratified squamous epithelium around the anus, distal to the dentate or pectinate line, that lacks sweat glands and hair follicles. This area is richly endowed with cutaneous sensory nerve endings.

It is hypothesized that anal fissures usually occur in the posterior midline secondary to a decreased vascular supply causing ischemia or a decreased number of external sphincter muscle fibers predisposing the posterior area to a weakness.¹² Constipation or a hard bowel movement causes a tear in the anoderm that causes pain. The tear often results in a vicious cycle of injury by exposing the underlying internal sphincter muscle. This results in spasms of the muscle which cause severe pain, results in further separation of the fissure edges, and possible further tearing during subsequent stool passage. A delay in wound healing may result and can ultimately lead to a chronic anal fissure.

Ischemia may contribute to the cycle of injury. The posterior midline, being the primary location for anal fissures, has less than half the blood flow compared to other quadrants in the anal canal.^{13,14} Individuals with chronic anal fissures have higher anal pressures than controls or patients with other colorectal disorders due to increased internal anal sphincter tone which results in blood flow reduction as well.¹⁵ These factors lead to the rationale for the use of topical nitroglycerin in treating anal fissures.

A tight anal sphincter is another hypothesis for the etiology of a fissure. Anal manometry in patients with fissures reveals an elevation of the resting anal canal pressures and infrequent spontaneous relaxation of the internal anal sphincter muscle.¹⁵ These high pressures can impede blood flow. The anodermal blood supply passes through the internal anal sphincter muscle and increased resting pressure may result in an ischemic ulcer or fissure.

An acute anal fissure has the appearance of a clean longitudinal tear in the anoderm with minimal inflammation (**Figure 85-1**). A chronic anal fissure is deeper, and exposed internal anal sphincter muscle fibers may be seen at its base. A skin tag or sentinel pile is usually seen externally and a hypertrophied anal papilla may be found at its upper aspect. Patients with a chronic anal fissure may also complain of anal discharge, pruritus, or “a lump.” Many people complaining to their physicians of bright red blood per rectum and anal pain think they are suffering from “hemorrhoids.” A good history and physical examination can confirm the diagnosis of an anal fissure. These patients will typically describe a sharp, burning, or shearing pain with defecation that lasts for a few moments up to an hour afterward. Some people will complain of a chronic ache that is exacerbated with a bowel movement. The prolonged pain is usually attributed to internal anal sphincter muscle spasm. Bright red blood is usually seen on the stool or toilet paper. Occasionally, a few drops of blood will fall into the toilet bowl.

Patients can usually describe the initial event that triggered the fissure as either an episode of constipation with a hard bowel movement or diarrhea. Most patients with a painful anal fissure will not tolerate a digital rectal examination or anoscopy. A close inspection of the anus can be performed after reassuring the patient and gently pulling the buttocks apart. An anal fissure with a sentinel pile, an abscess, or a thrombosed external hemorrhoid may also be seen. The application of anesthetic jelly may be required to examine the patient with an acute, painful anal fissure. Palpating the anal fissure with a gloved finger or cotton swab will reproduce the patient's pain.

INDICATIONS

Anal fissures are extremely painful and uncomfortable for the patient. They can cause poor job attendance or performance. All anal fissures should be treated when they are identified. Treatment relieves anal sphincter spasm and alleviates the ischemia to allow healing. The anal sphincter spasm can be relieved in the Emergency Department by injection, mechanical, neurotoxic, pharmacologic, or surgical methods. **Initial therapy is conservative, followed by topical medications, injection therapy, and then surgery.** Surgical treatment is

warranted for patients for whom nonoperative therapy fails, who have “chronic” anal fissures, or who experience severe anal pain.

CONTRAINDICATIONS

A patient with perianal Crohn's disease or ulcerative colitis is a relative contraindication to performing a lateral internal sphincterotomy. Medical management is advocated to initially treat these fissures associated with inflammatory bowel disease followed by the judicious use of an internal sphincterotomy.¹⁶ A patient who has had multiple fistulotomies in the past or a sphincteroplasty should have their anal sphincter evaluated by anal ultrasound or manometry. The patient may have marginal sphincter function, and an internal sphincterotomy can render them completely incontinent. A sphincterotomy should be performed only by a Colorectal Surgeon in these difficult patients.

EQUIPMENT

ANAL ANESTHESIA

- Povidone iodine or chlorhexidine solution
- 10 mL syringe
- 27 gauge needle, 2 inches long
- Local anesthetic solution with epinephrine
- 4×4 gauze squares
- Sodium bicarbonate solution

LATERAL INTERNAL SPHINCTEROTOMY

- Anal speculum
- #15 scalpel blade on a handle
- Metzenbaum scissors
- Forceps
- 4-0 chromic gut sutures

MISCELLANEOUS (DEPENDING ON TECHNIQUE)

- Topical nitroglycerine (0.2% to 2.0%)
- Topical nifedipine (0.2% to 2.0%)

FIGURE 85-2. The prone jackknife position. Note that the lower abdomen is not touching the edge of the table.

- Topical captopril (0.5%)
- Topical diltiazem (2%)
- Botulinum toxin
- #11 scalpel blade

DRESSING

- 4×4 gauze squares
- Gelfoam
- 2 inch adhesive tape

PATIENT PREPARATION

Explain to the patient and/or their representative the risks, benefits, complications, and options for treatment. The following discussion applies to the injection or surgical treatment of an anal fissure. Explain the postoperative care if a surgical technique is to be performed. Obtain an informed consent for the procedure. Undress the patient from the waist down. Place the patient prone or in the prone jackknife position (**Figure 85-2**). Tape the buttocks apart and to the procedure table to gain better exposure of the anus (**Figure 85-3**). Clean any dirt and debris from around the anus. Apply povidone iodine or chlorhexidine solution and allow it to dry. Place drapes to delineate a sterile field.

Perform an anal block. Mix 10 mL of local anesthetic solution with epinephrine in a syringe with 1 mL of sodium bicarbonate. This will decrease the burning sensation upon injection of the anesthetic solution. Inject the anesthetic solution into the subcutaneous tissue circumferentially around the anus, under the fissure, and laterally to anesthetize the pudendal nerves. The use of procedural sedation (Chapter 159) is recommended but not required.

TECHNIQUES

Begin the examination with a slow, gentle separation of the buttocks. This usually provides adequate visualization of the clean slit-like, acute anal fissure. The chronic fissure will appear similar to a deep ulcer with skin tags and enlarged anal papillae. Chronic fissures can be confused for external hemorrhoids when accompanied by a sentinel pile, which is a swollen external tag of skin at the base of the fissure. Test for adequate anesthesia. Inspect the lateral areas for an avascular area, usually on the right side between the right posterior

FIGURE 85-3. Taping the buttocks open in the prone patient allows for unobstructed access. The lateral traction strips are taped to the examination table or gurney.

FIGURE 85-4. The single-use disposable anal speculum. (Photo courtesy of OBP Medical.)

and right anterior hemorrhoid complexes. Palpate the intersphincteric groove in the avascular area. It is a palpable depression between the caudal ends of the internal and external anal sphincter muscles.

Anoscopy can be performed for enhanced visualization when necessary. Most patients have too much pain and involuntary sphincter spasm, which precludes a digital or anoscopic exam. Some require an exam under anesthesia. A proctoscopic exam may assist for ruling out secondary causes.

OBP Medical (Lawrence, MA) has recently developed a single-use, latex-free, nonsterile (clean), and disposable anal speculum (**Figure 85-4**). It is fully assembled with a built in LED light source and ready for use. Just pull the tab from the anal speculum to activate the light source for approximately 20 minutes. The advantages include no cleaning of specula, no worrying about contamination, no charger to plug into an outlet or find, no external light source, and no cords.

Atypical appearances of anal fissures, that might be eccentrically located, should prompt alternative diagnoses such as inflammatory bowel disease, ulcerative colitis, and Crohn's disease. Sexually transmitted infections such as chlamydia, gonorrhea, herpes, syphilis, and HIV, as well as tuberculosis, anal neoplasms, and sickle cell disease can present with anal fissures. If rectal bleeding is a prominent finding, endoscopy plus sigmoidoscopy or colonoscopy should be performed.

Management of an anal fissure begins conservatively.^{4,17} If unsuccessful, the next steps include topical preparations and injection therapy. A surgical sphincterotomy is the procedure of choice in refractory cases and has a 95% success rate.¹⁸

FOUR-FINGER ANAL STRETCH

In the past, a four-finger anal stretch technique was performed. This involved putting the index and long fingers of both hands into the patient's anal canal and pulling the anal canal forcibly open. This would often cause an uncontrolled tear in the internal anal sphincter muscle. Although patients had relief of their symptoms, 40% developed a recurrence of the fissure, and a significant proportion had some level of incontinence. **This technique is no longer recommended and should never be performed.** It is included only for the sake of completeness.

CONSERVATIVE MANAGEMENT

Most remedies for an anal fissure aim to alleviate internal sphincter hypertonia and anal pain. A trial of conservative treatment is employed for acute fissures and chronic fissures with mild to

moderate symptoms. This consists of bulk fiber supplements, stool softeners, a high-fiber diet, increased oral intake of water, sitz baths, heat, and topical anesthetics.^{4,19,20} The large, soft, bulky stools that result gently dilate the anal sphincter. Bulking agents and mild laxatives are 87% effective when used for 3 weeks.⁵ The combination can reduce recurrences if they are continued.⁵ The topical anesthetics and sitz baths in warm water after bowel movements will cleanse the area, alleviate the anal pain, and relieve internal anal sphincter muscle spasm. Topical anesthetics such as lidocaine gel may be soothing but are not more effective than fiber and sitz baths alone.²¹ Oral pain medications and muscle relaxants such as diazepam may be helpful. Suppositories are not recommended because they ascend to the rectal ampulla and do not effectively treat the problem within the anal canal. If an initial trial of conservative therapy for 4 weeks fails, the patient can undergo pharmacological therapy, injection therapy, or operative treatment.

A relatively new product is LEVORAG Emulgel (THD SpA, Italy) and which is available by prescription. It consists of a mixture of many ingredients in a 3.5 mL single-use tube with a built-in applicator. It acts like an emollient, lubricant, film-forming gel, and protectant that soothes when used twice a day for 3 weeks. Emulgel contains no anesthetics, cortisone, dyes, fragrances, or heavy metals. A pack or carton consists of 20 single-dose tubes.

TOPICAL PHARMACOLOGICAL TREATMENT

Nitric oxide has been identified as a chemical messenger mediating relaxation of the internal anal sphincter muscle. Patients treated with 0.2% glyceryl trinitrate ointment 2 to 3 times a day for 6 weeks to their lower anal canal (near the fissure) daily exhibited relief of their anal pain, reduced maximal anal resting pressure, and increased anodermal blood flow as measured by laser Doppler flowmetry.²² Topical nitroglycerin increases blood flow to the site, which is thought to result in less internal anal sphincter pressure, less pain, and a resultant improvement in healing rates in acute and chronic anal fissures.^{22,23} After 8 weeks, 68% of patients treated with glyceryl trinitrate had healed their fissures. Some studies have shown no significant difference in healing rates when compared to placebo.²⁴ However, up to 75% of patients will have an adverse reaction, mainly a headache unresponsive to mild pain relievers or develop a tolerance to the nitrate.²⁵ Up to 50% of patients will have a recurrence of an anal fissure after the initial anal fissure has healed with nitroglycerin treatment.^{26,27} The overall efficacy of nitroglycerine ranges from 47% to 86%.

Oral nifedipine, topical nifedipine (0.2% to 2.0%), oral diltiazem, topical diltiazem (2%), topical captopril (0.5%), and bethanechol have also been studied for the treatment of anal fissures.^{5,28-38} They were all found to be comparable to topical nitroglycerin and with fewer side effects. The US Food and Drug Administration approved 0.4% nitroglycerine ointment (Rectiv) for the treatment of anal fissures in 2012.^{18,39} The cost is approximately \$50.00 for a 30 gm tube.

Side effects such as headache, primary, may occur 10 minutes after application of topical nitroglycerin and typically last less than 30 minutes. Orthostatic hypotension and syncope have also been described in patients.¹⁸ Use of a glove or finger cot during the application of topical pharmacologic agents can prevent some systemic absorption and side effects. Patients taking phosphodiesterase type 5 (PDE5) inhibitors for erectile dysfunction (i.e., Cialis, Levitra, or Viagra) should not receive nitroglycerin-containing medications within 24 hours of their use due to the potential for life-threatening hypotension.^{18,39} After 24 hours, a lower concentration of nitroglycerin (e.g., 0.2% to 0.4% glyceryl trinitrate) is recommended compared to standard 2% ointments.

Topical nifedipine gel in a concentration of 0.2% used every 12 hours for 3 weeks has been successfully used to decrease anal

sphincter pressures and help heal fissures.⁴⁰ No systemic side effects or significant anorectal bleeding was observed in 141 patients treated with topical nifedipine.⁴⁰

BOTULINUM TOXIN

Botulin toxin is another pharmacological approach to the treatment of a chronic anal fissure. Botulinum toxin inhibits the release of acetylcholine from presynaptic nerve endings and has been shown to be a beneficial treatment for chronic anal fissures.^{5,41} Injection close to each side of the fissure improves healing rates.⁴¹ Inject 20 units of botulinum toxin A (Botox; Allergan, Irvine, CA) or 0.4 mL (50 U/mL) into the internal anal sphincter muscle on either side of the fissure using a 27 gauge needle. This technique has few side effects. Injection of high-dose (100 units) botulinum toxin A has also been used successfully.⁴ This can alleviate anal pain, decrease anal sphincter pressure, and promote healing.⁴² Unfortunately, this can result in some form of temporary incontinence for 2 to 6 months.^{18,41,43} The cost associated with the one-time injection is approximately \$400.00. If the underlying pathophysiology that led to the anal fissure is not addressed and corrected, a high rate of recurrence exists.^{4,17,44} The next step if botulinum toxin A injection fails is the sphincterotomy.

LATERAL INTERNAL SPHINCTEROTOMY

The mainstay of operative therapy is a lateral internal sphincterotomy. This technique is curative in over 95% of patients.^{18,45} This procedure can result in a transient incontinence of flatus and stool in most patients.⁴⁶ Unfortunately, approximately 15% of patients will be left with some form of permanent minor incontinence of flatus, stool smearing, and stool.²⁷ The technique divides the internal anal sphincter muscle between the dentate line and the anal verge. A meta-analysis of 2727 patients undergoing operative techniques for anal fissures revealed no significant difference between open versus closed lateral internal sphincterotomy for the persistence of fissure or incontinence.⁴⁷ However, significant differences were found when anal stretch was compared to all forms of sphincterotomy. The recurrence of an anal fissure after a sphincterotomy can often be cured by a re-do sphincterotomy.⁴⁸

A sphincterotomy requires some form of anesthesia. This is usually accomplished by an anal block injection. In some cases, usually due to anxiety and/or pain, the patient will require procedural sedation (chapter 159) or brief general anesthesia.

CLOSED LATERAL INTERNAL SPHINCTEROTOMY

The closed lateral internal sphincterotomy technique is preferred by some physicians (Figure 85-5). Its advantage is that a smaller wound is created. Unfortunately, this is a blind procedure and can result in injury to the patient and the physician.

Prepare the patient as described previously. **Place a well-lubricated anal speculum into the anal canal.** Open the speculum to provide a slight stretch to the anal sphincter muscles. Expose and view the left or right posterolateral quadrant of the anal canal. Place a gloved finger into the anal canal and palpate the internal aspect of the internal anal sphincter muscle. **Perform the remainder of this procedure while carefully palpating the course of the scalpel blade with the gloved finger in the anus.**

Insert a #11 scalpel blade horizontally through the skin and into the intersphincteric groove (Figure 85-5A). Advance the scalpel blade into the plane between the internal and external anal sphincter muscles and up to the level of the dentate line (Figure 85-5A). Direct the scalpel blade medially by turning it 90° (Figure 85-5B). Slowly divide the full thickness of the internal anal sphincter muscle while withdrawing the scalpel blade. **Do not cut the anoderm.**

FIGURE 85-5. The closed lateral internal sphincterotomy. **A.** The #11 scalpel blade is inserted horizontally between the internal and external anal sphincter muscles. **B.** The scalpel blade is turned 90° (1) then withdrawn (2) to transect the internal anal sphincter muscle.

Withdraw the scalpel from the anal canal. Remove the anal speculum. Close the incision site with one or two size 4-0 chromic gut interrupted sutures. Pack the anal canal with 4×4 gauze squares for 10 to 15 minutes to aid hemostasis and prevent the formation of a hematoma.

OPEN LATERAL INTERNAL SPHINCTEROTOMY

The open technique provides a clear exposure to the anatomy of the region. This is especially important for those less experienced with the procedure. It avoids the potential for injury to the physician when compared to the closed technique.

Prepare the patient as described previously. **Place a well-lubricated anal speculum into the anal canal.** Open the speculum to provide a slight stretch to the anal sphincters and view the fissure (**Figure 85-6A**). Rotate the speculum 90° to expose and view the left or right posterolateral quadrant of the anal canal (**Figure 85-6B**).

Place a gloved finger into the anal canal and palpate the internal aspect of the internal anal sphincter muscle.

Make a 1 cm longitudinal incision through the skin and subcutaneous tissue, between the dentate line and the anal verge (**Figure 85-6B**). This will center the edge of the internal anal sphincter muscle in the middle of the incision. Slide a scissors submucosally along the white internal anal sphincter muscle until the tips are at the level of the fissure, but not beyond the dentate line. Spread the arms of the scissors once to open the jaws of the scissors. Repeat this process on the other (deep) side of the internal sphincter muscle. Grasp and elevate the internal anal sphincter muscle with a forceps. Use a scissors to make a cut in the internal sphincter muscle the same length as the length of the anal fissure (**Figure 85-6C**).⁴⁹ **Do not completely transect the internal anal sphincter muscle. Preserve at least one-third of the proximal internal sphincter muscle intact.**⁴⁹

Pack the anal canal with 4×4 gauze squares to apply pressure to the area for 10 to 15 minutes to aid in hemostasis and to prevent

FIGURE 85-6. The open lateral internal sphincterotomy. **A.** The anoscope is inserted so that the anal fissure is visible. **B.** The anoscope has been rotated 90°. An incision has been made through the anoderm and subcutaneous tissue to expose the underlying anal sphincter muscles. **C.** The internal anal sphincter muscle is partially transected with a scissors. **D.** Closure of the incision.

the formation of a hematoma. Suture the incision closed with size 4-0 interrupted chromic gut (**Figure 85-6D**). Place a small piece of Gelfoam over the wound. Remove the anal speculum. Dress the incision site with 4×4 gauze squares.

ALTERNATIVE TECHNIQUES

There are several alternatives used to cure an anal fissure. Injection of a sclerosing agent in the office has had good results.⁵⁰ There is not enough information at this time to recommend the injection of a sclerosing agent in the Emergency Department. The combination of a fissurectomy with the injection of botulinum toxin A for a chronic anal fissure is as effective as a sphincterotomy.⁵¹ Reserved for a failed sphincterotomy is either a fissurectomy with primary closure or a fissurectomy with a flap repair (e.g., V-Y flap or island flap).^{4,48}

AFTERCARE

Instruct the patient to remove the dressing in 12 to 24 hours or before a bowel movement. Warm sitz baths four times a day will keep the area clean and alleviate any pain. Prescribe a high-fiber diet with oral stool softener supplements to keep the stools soft and bulky. Oral analgesics such as acetaminophen or nonsteroidal anti-inflammatory medications with supplementary narcotic analgesics will often ease the immediate and postoperative pain. The patient should follow up in 1 to 2 weeks for reevaluation. The patient should immediately return to the Emergency Department if a fever, severe pain, or bleeding from the incision site develops.

COMPLICATIONS

Many complications have been associated with a lateral sphincterotomy. Itching, burning, bleeding, delayed wound healing, and constipation are minor problems. The patient may complain of mucus drainage or fecal soiling during the healing phase. Bulking agents or a high-fiber diet may help decrease the drainage. Recurrent fissures occur in about 8% of patients, 66% of which heal with conservative treatment. Up to 45% of patients may experience some degree of incontinence, but only 3% of patients may have their life affected.⁵² Incontinence can persist.²⁷ A fecal impaction, abscess, or hemorrhage can become significant. Enemas are useful for the constipated patient. An abscess should be incised and drained, preferably in the Operating Room for adequate anesthesia to completely explore the wound and debride any necrotic tissue. A subcutaneous fistula can develop if the anoderm is violated during the sphincterotomy and not recognized. This is easily taken care of by doing a fistulotomy of this superficial skin bridge. The physician may be injured while performing the closed technique. This technique should be reserved for those with experience and a patient who is sedated to decrease the chances of injury.

SUMMARY

There is no perfect treatment for an anal fissure. Anal pain with bleeding due to an anal fissure is initially treated conservatively with a high-fiber diet, stool softeners, and warm sitz baths. Most patients will respond to these measures. A few will fail conservative therapy and need pharmacological or operative therapy. A sphincterotomy remains the best curative procedure, but is also the most invasive. The goal of all the different regimens is to decrease anal pain, reduce anal sphincter spasm, and heal the fissure.

External Hemorrhoid Management

Katherine Holmes, Michael Balkin, and Hao Wang

INTRODUCTION

Thrombosed external hemorrhoids consistently cause patient pain and embarrassment. The etiology is still unclear. The mainstay of treatment is excision. **It is important to remember that excision is performed to alleviate or palliate pain and shorten the course of the disease.** The natural history of an untreated thrombosed external hemorrhoid is to rupture and spontaneously evacuate the clot or to resorb the clot over time. Therefore, treatment should give the maximum amount of pain relief with the least chance of complications. To make this decision, it is important to take a thorough history

from the patient and include questions about the time course, severity, improvement or deterioration, and what has worked or failed in the past. **It is also important to perform a physical examination to rule out prolapsed grade IV internal hemorrhoids, perianal abscesses, and other perianal masses.**

ANATOMY AND PATHOPHYSIOLOGY

External hemorrhoids fall into three main groups: left lateral, right anterior, and right posterior (**Figure 86-1**).¹ They are covered with anoderm and visible on the outside of the anal canal. They are composed of a venous plexus mixed with connective tissue. External hemorrhoids drain into the middle and inferior rectal veins that terminate into the internal iliac and femoral veins, respectively. **External hemorrhoids do not prolapse like internal hemorrhoids. They engorge and thrombose to cause significant pain and discomfort. It will not benefit the patient to try to reduce an external hemorrhoid since their normal location is mostly outside the anal canal and reduction will not remove the clot. External hemorrhoids are never covered with mucosa.** The overlying skin may appear to look shiny, swollen, gangrenous, or like an orange peel mimicking the look of mucosa.

It is important to differentiate internal versus external hemorrhoids. Internal hemorrhoids originate above the dentate line, lack sensation, and are covered with rectal mucosa. Prolapsed internal hemorrhoids are painless unless they become gangrenous, infected, strangulated, or thrombosed. External hemorrhoids originate below the dentate line, have sensory innervation, and are covered with squamous epithelium that matches the surrounding skin.

The patient usually complains of a history of sudden onset of pain and swelling. The exact cause of thrombosed external hemorrhoids is unknown.² Some studies have shown correlations between thrombosed external hemorrhoids and constipation, excess straining during defecation, and strenuous exercise (e.g., bicycling, jogging, or weight lifting). Since this disease process affects younger individuals more frequently, it seems that intense physical activity plays a more prominent role than does constipation or straining to defecate.

External hemorrhoids can be diagnosed when a patient complains of sudden onset of pain, swelling, and usually no bleeding.

FIGURE 86-2. Thrombosed external hemorrhoid management. **A.** The thrombosed external hemorrhoid. **B.** Injection of local anesthetic. **C.** The incision is made. **D.** Expelling the blood clot. (Used with permission from reference 3.)

The physical examination will reveal a tensely swollen area covered with anoderm. The swelling will be visible by gently spreading the buttocks and inspecting the area near the anal canal. They have a bluish coloration, especially in patients with little skin pigmentation, and almost no redness (**Figure 86-2A**). The swelling is abrupt and looks like placing a marble under a sheet and tucking in the edges. **This differentiates the appearance of a thrombosed external hemorrhoid from the appearance of an abscess that would have erythema and gently sloping sides from edema.**

INDICATIONS

The primary indication for the excision of a thrombosed external hemorrhoid is pain.³⁻⁸ The excision should occur as soon as possible from the onset of pain and is usually not indicated after the fourth day when the clot is already being absorbed and the risks associated with surgery may outweigh the benefits.⁹ Improving pain suggests that medical management is the more appropriate method of care as thrombosed external hemorrhoids will spontaneously resolve in

a few weeks with no complications. Medical management includes bulk-forming fiber supplements (e.g., Citrucel [methylcellulose], Fibercon [polycarbophil], Metamucil [psyllium], and Benefiber [wheat dextrin]), sitz baths, stool softeners (e.g., Colace or docusate sodium), topical corticosteroids (e.g., Proctofoam HC, Proctosol HC, Preparation H, or Anusol HC), 0.2% glyceryl trinitrate (GTN), nifedipine, and over-the-counter hemorrhoidal astringents containing witch hazel (e.g., Preparation H pads and Tucks pads).^{1,5,6,10} It is important to note that thromboses lasting for less than 72 hours should be evaluated for excision.^{3,4,7} Surgery significantly reduces the disease time course and severity. There is a small subgroup of patients who do not seem to improve with medical management and will require excision late in the course of the disease. Surgical excision has a lower frequency of recurrence and a longer time interval to recurrence than conservative treatment.¹¹ The thrombosis to be excised should involve 1 or 2 hemorrhoids at most.

CONTRAINDICATIONS

There are several contraindications to the Emergency Department incision and drainage of a thrombosed external hemorrhoid.¹² Grade IV internal hemorrhoids associated with thrombosed external hemorrhoids, circumferential hemorrhoids, or very large thrombosed external hemorrhoids should be managed by a Surgeon in the Operating Room using electrocautery or suture ligation to control hemorrhage and provide anesthesia. Patients taking anticoagulants require meticulous care and possible reversal of the coagulopathy. An allergy to local anesthetic agents will require a trip to the Operating Room to excise the hemorrhoid. **Painless masses are never thrombosed external hemorrhoids and require evaluation by a Surgeon.** Draining external hemorrhoids should be followed-up in 24 hours by a Surgeon. Patients who are unable to cooperate with the procedure may require procedural sedation (Chapter 159) or general anesthesia. A Surgeon should manage patients who have thrombosed external hemorrhoids and also have inflammatory bowel disease, anorectal fissures, anal fistulas, cirrhosis, perianal infections, portal hypertension, rectal prolapse, anorectal tumors, or who are immunocompromised. Patients with external hemorrhoids that are not thrombosed usually require no treatment. They may need medical care and appropriate referral for their anal pain. Discuss the management of pregnant patients with an Obstetrician and Colorectal Surgeon before incising a thrombosed hemorrhoid.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution with epinephrine
- 5 mL syringe
- 25 gauge needle
- 18 gauge needle
- #11 scalpel blade on a handle
- 4×4 gauze squares
- 2–0 absorbable sutures (e.g., Vicryl, Dexon, chromic gut, or plain gut)
- 3–0 absorbable sutures (e.g., Vicryl, Dexon, chromic gut, or plain gut)
- Small dissecting scissors
- Small grasping forceps
- 2 inch adhesive tape
- Tincture of benzoin
- Silver nitrate applicator sticks

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. It is also important to explain what to expect after the procedure. Obtain an informed consent for the procedure. This procedure may cause the patient significant anxiety and embarrassment. A thoughtful and gentle approach is recommended.

It is crucial to position the patient so that the anus is clearly visible and the Emergency Physician can work with both hands.¹³ Place the patient in the prone or prone jackknife position with their hips flexed (Figure 86-3). Tape the buttocks to the procedure table (Figure 86-4). Apply tincture of benzoin to the buttocks and allow it to dry. Place strips of 2 inch adhesive tape on the left and

FIGURE 86-4. Taping the buttocks open in the prone patient allows for unobstructed access. The lateral traction strips are taped to the examination table or gurney.

FIGURE 86-5. Excision of the thrombosed external hemorrhoid. **A.** The dotted line represents the incision lines to remove the skin and underlying thrombosis. **B.** Injection of local anesthetic solution. **C.** The skin incision has already been performed. The skin and underlying thrombosis are dissected free with a scissors. **D.** The ellipse of skin and the underlying thrombosis have been removed. The fibers of the underlying external anal sphincter muscle are visible.

right cheeks of the buttocks and perpendicular to the anus. Apply lateral and slightly cranial traction with adhesive tape to get the proper exposure. Attach the distal ends of the tape to the procedure table or stretcher to maintain exposure during the procedure. This positioning works best in the Operating Room when the patient is under anesthesia and unlikely to move. Explain to the patient that they must relax and refrain from squeezing their buttocks shut. It is very difficult to stop and reposition the patient to place a suture for hemorrhage control if the patient is poorly positioned and there is difficulty with hemorrhage in the middle of the procedure. Apply drapes to protect the patient and clothing from spills. Clean the anus and surrounding area of any dirt, debris, and stool. Apply povidone iodine or chlorhexidine solution and allow it to dry.

The patient usually is in significant pain. The injection of local anesthetic solution can be excruciating (**Figures 86-2B and 86-5B**). Consider the use of ice packs to the area for 5 to 10 minutes before injection, intravenous analgesics, sedatives, or procedural sedation (Chapter 159). This will be greatly appreciated by the patient.

TECHNIQUE

Determine the area of the incision. **The best pain relief will be achieved if the thrombosis is excised rather than incised.**¹⁴ If the hemorrhoid is very large, one-third or greater of the anal circumference, it is best to excise the middle third of the hemorrhoid leaving as much anoderm as possible to prevent the wound healing with a stricture. Excision can be achieved with two radial incisions starting near the center of the anus and enclosing an ellipse of skin that will be removed with the thrombosis (**Figure 86-5A**).

Inject local anesthetic solution containing epinephrine starting laterally and injecting medially to and beyond the thrombosed hemorrhoid (**Figures 86-2B and 86-5B**).⁹ The injection should include both lines of the planned incision and, if possible, the area medial to the thrombosis. The local anesthetic agent should also cross the midline anteriorly and posteriorly to include nerve fibers crossing over from the opposite side of the anus. Allow 5 minutes for the

local anesthetic to take effect. The degree of local anesthesia can be checked by pinprick or by pinching the thrombosed hemorrhoid with forceps.

Make the incisions with a #11 scalpel blade when satisfactory local anesthesia has been achieved (**Figure 86-2C**). Dissect the ellipse of skin and the underlying clot from lateral to medial with a scissors (**Figure 86-5C**). **Do not cut the anal sphincter at the base of the wound (Figure 86-5D). It is important to remove the entire clot since the purpose of the excision is only to palliate the patient's pain (Figures 86-2D and 86-5D).** Small clots in or between the sphincter muscles may still cause considerable pain. These can be grasped with fine forceps and removed.

Examine the wound carefully for hemostasis. Localized areas of bleeding can often be controlled with the application of silver nitrate to cauterize the wound. It is the editor's personal belief that there is less discomfort if silver nitrate is used for hemostasis than if one is forced to use suture ligation. A 3-0 absorbable suture can be used in a figure-of-eight formation over the area of continued bleeding. Plain catgut is preferred because the suture will dissolve very quickly. A suture that remains in place for several weeks in this area can sometimes be very uncomfortable for the patient. Dress the wound with three or four gauze squares folded in half and one piece of tape across the buttocks to hold the dressing in place.

AFTERCARE

The patient should leave the dressing in place until the next day or the next bowel movement. It is best to remove the dressing in a sitz bath and replace it with dry 4×4 gauze placed between the buttocks to collect any moisture. Tape is usually not necessary. Encourage the patient to take three or four sitz baths per day and after every bowel movement. Instruct the patient to use warm water and bathe for 20 minutes each time. The sitz bath serves two functions. It keeps the wound clean and helps relax the internal anal sphincter muscle spasm to help relieve the pain. An alternative to wiping after bowel movements and sitz baths is to shower. The shower will gently wash

away any material and not hurt like wiping. Continue the sitz baths and dressing changes until the wound is healed.

Fiber supplements and stool softeners should be continued for at least 6 weeks.¹ Prescribe 1 tablespoon of psyllium products (e.g., Metamucil) with water twice a day to soften and bulk the stool. The goal is to achieve an atraumatic stool that gently dilates the anus as it passes. If the patient is unable to tolerate psyllium, 100 mg of docusate orally once or twice a day can be used to soften the stool but will not provide the bulk.

The patient should feel much less pain after the thrombosed hemorrhoid is excised. The remaining pain can frequently be controlled with the sitz baths. Some form of oral analgesia is required. Acetaminophen or ibuprofen is usually adequate. The use of codeine or opiates has a pronounced constipating effect that could result in painful bowel movements. Do not prescribe narcotic analgesics for more than 24 hours. The patient should return to the Emergency Department if the pain is not improved, if bleeding continues, or if they develop a fever. The wound must be watched for any signs of infection.

COMPLICATIONS

The rate of complications for excision of thrombosed external hemorrhoids is not well reported.¹⁵⁻¹⁸ Reported complication rates for more major anal surgery show bleeding occurs in 1.5% to 4.0% of patients and infection occurs in 2% of patients.^{11,15,16} This is a very low rate of infection considering the persistent fecal contamination at the anus. We estimate the complication rate for the excision of a thrombosed external hemorrhoid would be even less.

Any post-hemorrhoidectomy bleeding that is minimal can be managed by the application of local pressure. Moderate to severe bleeding will require surgical cauterization or the insertion of a commercially available post-hemorrhoidectomy pack.¹⁹ This is an accordion-like pack that is inserted through the anoscope and into the anal canal. Pulling the two strings of the pack accords the pack down into the anal canal to tamponade the bleeding. A Foley catheter may be substituted if the packs are not available. These patients require intravenous analgesics, intravenous sedation, and hospitalization.

The treatment for a patient with an infection in the perianal area who has not had surgery is to open the abscess and place the patient on sitz baths. Infection is very unlikely since the wound is already open from the excision procedure and the patient is taking sitz baths. Broad-spectrum antibiotics for aerobic and anaerobic bacteria should be given to any patient with a postprocedural infection and the wound examined under general anesthesia to rule out any underlying pathology.

Long-term theoretical complications include stricture and incontinence. These are exceedingly rare and can be prevented by not removing too much anoderm and not injuring the underlying external anal sphincter muscle.

The use of a linear incision should be avoided.²⁰ The stretched skin will close and create a pocket in which a hematoma or abscess can form. Removal of clots through a linear incision is often difficult, inadequate, and may lead to a higher incidence of recurrence. **Always make an elliptical incision.**²⁰

SUMMARY

External hemorrhoids may thrombose and cause the patient considerable pain, discomfort, anxiety, and embarrassment. The natural history of this disease is for the clot to drain or resorb without significant long-term morbidity. Excision of the thrombosed external hemorrhoid will provide considerable relief if the patient presents acutely and within 2 to 3 days from the onset of symptoms. It is important to achieve good hemostasis and not damage the underlying external anal sphincter muscle or remove too much anoderm to

avoid problems with continence or stricture formation. An elliptical excision is far superior to a linear incision as more clot can be expressed through the linear incision with fewer surgical complications. Fiber supplements and sitz baths should be prescribed rather than surgical excision if the patient presents later in the course of the disease.

Prolapsed Rectum Reduction

Jamil D. Bayram and Eric F. Reichman

INTRODUCTION

Rectal prolapse is an uncommon condition (**Figure 87-1**). It was first described in the Bible (2 Chronicles 21). "You yourself will be very ill with a lingering disease of the bowels, until the disease causes your bowels to come out. . . . After all this, the Lord afflicted Jehoram with an incurable disease of the bowels. In the course of time, at the end of the second year, his bowels came out because of the disease,

FIGURE 87-1. A patient with a rectal prolapse. (Used with permission from Knoop KJ, et al (eds): *The Atlas of Emergency Medicine*, 3rd ed. New York: McGraw-Hill, 2010. Photo contributor: Alan B. Storrow, MD.)

and he died in great pain.” The pathophysiology of a rectal prolapse has been evolving since 1543 when Vesalius described the detailed anatomy of the anorectum. Today, three types of rectal prolapse are recognized, and they represent three stages of a continuum.¹

Rectal prolapse usually affects people at the extremes of age.² It is most common in the very young and the elderly. The condition usually manifests itself in children within the first 4 years of life, with the highest incidence occurring in the first year.³ The gender incidence in children is equal but slightly weighted toward males.¹ The peak incidence in the elderly is approximately between 60 and

70 years of age. It affects primarily elderly women, with a 6:1 ratio of females to males.⁴

ANATOMY AND PATHOPHYSIOLOGY

A rectal prolapse is classified into one of three stages (**Figure 87-2**). An internal prolapse is the prolapse of the upper rectum and sigmoid colon into the rectal ampulla (**Figure 87-2A**). It is also known as a hidden or occult prolapse. This type of prolapse does not emerge through the anus. Mucosal prolapse is more common in children. It results from the loose attachment of the mucosa to the submucosal layers and an associated weakness of the anal sphincter. A mucosal prolapse is diagnosed by the presence of radial folds and the absence of muscular wall.⁴

If the condition progresses, it leads to the protrusion of part or all layers of the rectum through the anal orifice. If only the mucosa is prolapsed, it is classified as an incomplete prolapse (**Figures 87-2B and 87-2C**). Synonyms include mucosal prolapse and partial prolapse. A complete rectal prolapse occurs when all bowel layers, including the muscular wall, are involved (**Figures 87-2D and 87-2E**). This condition is also known as a procidentia. The complete rectal prolapse is more common in the elderly. It results from generalized weakening of the pelvic floor and anal sphincter muscles. A complete rectal prolapse is characterized by the presence of concentric folds. A double-thickness muscular wall will be felt upon palpation.⁵

Numerous risk factors are associated with a rectal prolapse.⁵⁻¹³ These include malnutrition, chronic constipation, excessive straining, and diarrheal disorders such as amoebiasis, giardiasis, and other parasitic infections. Rectal prolapse in children is often idiopathic. However, there is an association with paraplegia, meningomyelocele, and pinworms. Anatomic variations such as a vertical course of the

FIGURE 87-2. Types of rectal prolapse. **A.** Midsagittal view of the internal, hidden, or occult prolapse. **B.** Midsagittal view of the incomplete, mucosal, or partial prolapse. **C.** Posterior view of the incomplete, mucosal, or partial prolapse. **D.** Midsagittal view of the complete prolapse or procidentia. **E.** Posterior view of the complete prolapse or procidentia.

rectum, flat sacrum and coccyx, and lack of levator ani support can also result in a rectal prolapse. Children placed on adult toilet seats for prolonged periods of time may develop a rectal prolapse. One of the most serious risk factors for a rectal prolapse in children is cystic fibrosis.⁷ Patients with cystic fibrosis have an 18% incidence of rectal prolapse. Children with no apparent cause for a rectal prolapse should be considered for a sweat chloride test. In the elderly, rectal prolapse is associated with collagen vascular diseases, malignancy, pelvic floor weakness, mental retardation, organic brain syndrome, stroke, chronic psychiatric conditions, and chronic neurologic conditions (e.g., tabes dorsalis, cauda equina, and multiple sclerosis).^{6,12} It is important to note that patients with a rectal prolapse often present with no apparent causes. The physician should maintain a high index of suspicion for the risk factors mentioned above.

The diagnosis can be difficult in the early stages when the prolapse remains in the upper canal (i.e., internal or hidden prolapse). The patient may complain of anorectal pain, back pain, discomfort during defecation, difficulty initiating a bowel movement, feeling of incomplete evacuation, tenesmus, pelvic fullness or pain, bloody discharge, or mucoid discharge. At this stage, asking the patient to strain may provoke the prolapse.

The diagnosis becomes easier in a partial or complete prolapse because it protrudes through the anus (**Figures 87-2C and 87-2E**). These patients may complain of an anal mass when they sit, stand, or walk.^{1,5} It is usually the parents of young children who note the anal mass during defecation, although this may also be the complaint of an adolescent or adult.² The Emergency Physician should consider the mass described by the parents to be a rectal prolapse if the physical examination is negative.³ Spontaneous reduction will often occur in this age group. It might be noted as an incidental finding on physical examination.

The differential diagnosis of a rectal prolapse includes anal warts, hemorrhoids, intussusception, prolapsed rectal polyp, a prolapsed rectal tumor, or a small bowel eversion.¹⁴⁻¹⁸ **Mistaking an intussusception for a rectal prolapse may result in significant morbidity and mortality.**¹⁹⁻²² **Differentiating features of an intussusception include the ability to pass the finger between the prolapsed bowel and the anal sphincter (Figure 87-3). This is in contrast to patients with a rectal prolapse in which the protruding mucosa is continuous with the perianal skin and the examiner's finger will not pass that junction (Figure 87-2D).**^{1,3,8} Patients with an intussusception usually appear ill, whereas those with a rectal prolapse appear well.³ Prolapsing hemorrhoids are more often

FIGURE 87-3. An intussusception. Note the junction where the finger can be passed (arrows).

seen in adolescents and adults, are usually purple in color, have deep grooves between the areas of prolapsing tissue, and lack radial or concentric folds. A prolapsed polyp or tumor is plum-colored, does not involve the entire anal circumference, is movable, and is usually palpable as a small growth on a stalk.^{3,9}

INDICATIONS

Reduction should be attempted on all patients with a visible rectal prolapse as soon as possible to avoid vascular compromise of the bowel. It is easier to reduce before edema occurs from prolonged prolapse. Early reduction may avoid complications and stretch damage to the pelvic floor ligaments, the pelvic floor muscles, and the anal sphincter muscles.

CONTRAINDICATIONS

There are few absolute contraindications to the reduction of a rectal prolapse. Gangrene, necrosis, and ulceration of the mucosa are signs of vascular compromise or ischemia and require an emergent consultation by a General Surgeon or Colorectal Surgeon. **Do not reduce ischemic tissue as it may precipitate peritonitis or cause a perforation of the rectum. If the Surgeon's arrival is delayed, prompt gentle reduction should be attempted only after discussions with the Surgeon. Do not reduce an intussusception.** Consult a Surgeon for further evaluation and management of an intussusception.

EQUIPMENT

- Gloves
- Water-soluble lubricant
- 4×4 gauze squares
- 2 inch wide adhesive tape
- Benzoin spray or swabs
- Sedatives as necessary

PATIENT PREPARATION

Explain the reduction procedure to the patient and/or their representative. Reduction is most likely successful in a relaxed and non-straining patient. Sedation may sometimes be required in adults. Sedation is more often needed in pediatric patients. Children tend to be more anxious, crying, fighting, or straining, all of which will increase the intraabdominal pressure and make reduction more difficult. The sedation may be administered intramuscularly, intravenously, orally, or subcutaneously.

Position the patient.^{9,10} Place the child in the prone knee-chest position on the parent's lap or on the examination table (**Figure 87-4**).

FIGURE 87-4. The prone knee-chest position for children.

FIGURE 87-5. Taping the buttocks open in the prone patient allows for unobstructed access. The lateral traction strips are taped to the gurney or examination table.

Place the adult patient in the prone position on an examination table. Large buttocks or tense buttocks may interfere with the reduction of a prolapsed rectum. In these cases, apply benzoin to the buttocks and allow it to dry. Tape the buttocks open for better access (**Figure 87-5**). Alternatively, in both age groups, the patient can be placed in the lateral decubitus position.

TECHNIQUE

Position the patient. Liberally apply water-soluble lubricant onto the prolapsed rectum. Apply gauze squares onto the prolapsed tissue at the 3 o'clock and 9 o'clock positions (**Figure 87-6**). The bowel wall is quite slippery after lubrication, and the gauze will improve the grip on the mucosa. Place both thumbs near the bowel lumen with the hands stabilized on the buttocks (**Figure 87-6A**). Apply steady, gentle thumb pressure to gently roll the prolapsed rectum back through the anus. Alternatively, the index and the middle fingers can be used to reduce the prolapsed rectum (**Figure 87-6B**). **Regardless of the method used, constant and steady pressure must be applied to**

the prolapse. The reduction often requires patience as it may take up to 15 minutes to reduce a prolapsed rectum.

The rectum will become edematous, and swelling will be noted if the rectal mucosa has been prolapsed for a prolonged period of time. Wrap a gauze square or an elastic wrap around the prolapsed rectum and apply gentle manual compression for 3 to 5 minutes before attempting the reduction.²³ If the first effort is unsuccessful without sedation, a second attempt at reduction after administering sedation is appropriate. If the prolapsed rectum will not reduce (i.e., incarcerated), consult a General Surgeon or Colorectal Surgeon for reduction under general anesthesia and possible surgical repair.

ALTERNATIVE TECHNIQUES

A novel method to help reduce a prolapsed rectum uses simple table sugar.²⁴⁻²⁶ The longer the rectum is prolapsed, the more edematous it becomes and the more difficult it is to reduce. Apply a liberal amount of sugar onto the prolapsed rectum and cover it with several layers of gauze. Allow the patient to relax for 15 to 30 minutes. The hyperosmotic sugar draws fluid out from the edematous prolapsed rectum. Gently wipe off the sugar with saline- or water-moistened gauze. Attempt manual reduction as described above.

ASSESSMENT

Perform a digital rectal examination to ensure that the reduction is complete.⁹ If not, apply pressure with the examination finger to completely reduce the prolapse. The digital rectal examination should be followed by anoscopy in the Emergency Department to look for any gross pathology. Refer to Chapter 88 for the complete details of anoscopy.

AFTERCARE

The application of a bulky pressure dressing will prevent an acute recurrence of the prolapse. Apply petrolatum gauze over the anus. Apply several gauze squares over the petrolatum gauze and into the gluteal cleft. Tape the buttocks together. **The patient and the family must be informed that reduction might be temporary and the prolapse could recur.** Training cooperative parents to reduce the prolapse is warranted in cases of recurrent rectal prolapse in the pediatric age group. Be sure to send them home with gauze squares, gloves, and lubricant.

The underlying cause of the rectal prolapse should be treated.²⁷ A prophylactic regimen of laxatives and stool softeners should be started if the patient is constipated. Instruct the patient on proper eating habits including fruits, vegetables, and roughage. In cases of diarrhea, treatment should target the underlying causes. Seating

FIGURE 87-6. Rectal prolapse reduction techniques. **A.** Thumb method. **B.** Finger method.

children on a child's potty-chair or on an adult toilet seat with a small hole may prevent future episodes of rectal prolapse. Discourage excessive squatting and straining.⁴

All patients who have undergone successful reduction should be referred to a Colorectal Surgeon for further evaluation.²⁸⁻³¹ Children should be followed up to rule out serious etiologies such as cystic fibrosis. As the child grows, the supporting tissue around the rectum develops. Therefore, rectal prolapse in this age group is usually self-limited and surgery is rarely required. Adults should be referred for proctosigmoidoscopy to rule out a tumor. Conservative management in the elderly is rarely successful, and most patients eventually require surgical repair. Early referral can avoid complications and stretch damage to the pelvic floor ligaments, pelvic floor muscles, and anal sphincter muscles.

COMPLICATIONS

The complications of the procedure are often minimal. The reduction itself may lead to minimal mucosal bleeding that is self-limited. The patient may experience a slight discomfort in the anus for up to 24 hours after the reduction. This can be managed with oral acetaminophen or nonsteroidal anti-inflammatory drugs.

The inability to reduce a rectal prolapse is an indication for surgical consultation in the Emergency Department. An incarcerated rectal prolapse can lead to vascular compromise. Signs of vascular compromise include mucosal gangrene, necrosis, and ulceration. These patients require admission to the hospital with an emergent surgical consultation, even if the reduction is felt to be successful, due to the risk of reducing ischemic bowel that could perforate. The rupture of an incarcerated rectal prolapse with small bowel herniation through the tear has very rarely been reported during attempted reduction.¹¹ Fecal and urinary incontinence may also occur as a result of a long-standing prolapse. This is due to the entrapment and stretching of the pudendal or perineal nerve resulting in neurovascular dysfunction and not a complication of the reduction procedure.

SUMMARY

A rectal prolapse is an uncommon condition affecting the very young and the elderly. Reduction can usually be performed in the Emergency Department. It is important to differentiate a prolapsed rectum from an intussusception and from external hemorrhoids. The reduction procedure is quick and simple. The application of constant, firm, and gentle pressure to the rectum in a relaxed and nonstraining patient will reduce most rectal prolapses. All patients with a prolapsed rectum should be referred for further evaluation to rule out underlying pathologic causes for the prolapse.

Anoscopy

Charles Huggins, Claudia Kim, and Hao Wang

INTRODUCTION

Examination of the anal canal is important to evaluate several common patient complaints relating to the anus including bleeding, itching, and pain.^{1,2} It is possible to examine parts of this area with flexible instruments or a rigid rectosigmoidoscope. The only method that will give a consistent clear view of the anal canal is anoscopy.³ To properly perform anoscopy, it is necessary to thoroughly understand the anatomy of the region, be aware of the possible causes of

FIGURE 88-1. The topical anatomy of the anal canal.

the symptoms evaluated, use the appropriate equipment, and position the patient correctly.

ANATOMY AND PATHOPHYSIOLOGY

It is necessary to understand the anatomy of the anal canal in order to evaluate the patient's signs and symptoms properly.⁴ The anal canal is completely extraperitoneal and is approximately 2.5 to 4 cm long. The anatomy can be divided into topical anatomy and major supporting structures.⁵ The topical anatomy is depicted in **Figure 88-1**.

Perineal skin covers the perineum, is fully innervated, and includes both hair follicles and apocrine glands. It can be grossly

distinguished from the anoderm surrounding the anal canal by the visible hair. The anoderm is specialized squamous epithelium that lines the majority of the anal canal. It is fully innervated but does not have apocrine glands or hair follicles. This epithelium is very thin and elastic, and if it is destroyed by surgery or infection, stricture formation during healing may occur.

Looking into the anal canal, the anoderm can be seen to end in an irregular line called the dentate line (**Figure 88-1**). This is a demarcation of anoderm to transition zone mucosa. The anal canal proximal to the dentate line is lined with columnar epithelium. It has no cutaneous sensation and is insensitive to cutting. This allows minor therapeutic procedures (e.g., banding or suture ligation) to be done without an anesthetic agent. It is also the reason internal hemorrhoids usually do not cause pain. The transition zone continues proximally for a variable length of 6 to 12 mm before it becomes the rectal mucosa (**Figure 88-1**). The junction of the transitional zone with the rectal mucosa is not visible to the naked eye. The rectal mucosa decreases in diameter in the area of the transitional zone. The mucosa appears to be bunched together in columns called the columns of Morgagni at the level of the dentate line (**Figures 88-1 and 88-2**). Crypts are formed between the columns as the transitional zone becomes the dentate line. Under the anoderm in the crypts are multiple anal glands. Blockage of the anal glands by foreign material leads to infection. Blockage or primary infection of the glands causes the majority of abscesses that arise around the anus. The crypts are areas to look for foreign bodies (e.g., fish or chicken bones).

External hemorrhoids are located in the left-lateral, right-posterior, and right-anterior portions of the distal anal canal and are covered with anoderm. Their normal position is below the dentate line and they can be examined by gently spreading the buttocks. The internal hemorrhoids also are located at the left-lateral, right-posterior, and right-anterior positions. They are normally located above the dentate line and are covered with transitional epithelium and rectal mucosa. They can best be examined with an anoscope if they are not prolapsed. It is possible to see them with a retroflexed

FIGURE 88-2. The major supporting structures of the anal canal.

sigmoidoscope or colonoscope, but the increased air pressure tends to flatten them out giving a false impression of their size.

The anoscope is used to examine the closed portion of the anal canal. It dilates the anal sphincter and allows one to examine the underlying canal through an opening cut out from the side of the anoscope called a fenestration. It is important to understand the anatomy and functions of the anal sphincter musculature to properly perform this examination (**Figure 88-2**). Immediately below the anoderm is the internal anal sphincter muscle. It is circumferential and consists of a thickening and rounding of the continuation of circular smooth muscle from the rectum. This muscle is not under conscious control. The first response of the internal anal sphincter muscle to a rectal examination or anoscopy is contraction. **It is necessary to pause and use slow gentle dilatation to prevent patient discomfort and complete the examination.** The axis of the anal canal will normally follow an imaginary line drawn from the patient's anus to their umbilicus. Surrounding the internal anal sphincter muscle is the external anal sphincter muscle. This is comprised of three external sphincters of striated muscle that are more loop-like than circumferential. Deep to these muscles and at the top of the anal canal is the puborectalis muscle. This forms a sling to pull the anus anterior. It is connected to both the anal sphincters and the levator ani group of muscles. The puborectalis muscle can be felt as a funnel-shaped structure during the digital rectal examination.

INDICATIONS

Anoscopy is indicated for the evaluation of most anal symptoms.¹⁻¹⁰ There are numerous common complaints and conditions where an anoscope, in conjunction with visualization and a digital rectal examination, would be used for evaluation or therapy.⁶⁻⁸ Anoscopy can be used diagnostically to evaluate rectal bleeding, itching, discharge, fecal impaction, anal pain, pain with defecation, perirectal infections, fistulas, foreign bodies, internal hemorrhoids, anal masses, and abnormal digital rectal examinations. It can also be used for the evaluation of uncomplicated anal trauma, inflammatory bowel disease, and sexual abuse. Anoscopy can be used therapeutically to open the anus and allow the application of medications, procedures to be performed, or observation of anal pathology management (e.g., anal fissures, anal fistulas, intraanal condylomata, and hemorrhoids).

CONTRAINDICATIONS

Most contraindications to anoscopy are relative. Anoscopy should not be performed in unwilling patients, patients with unstable medical conditions, or patients who are immunosuppressed. The amount of discomfort a patient will undergo relates to their tolerance. Minor discomfort associated with topical skin excoriations can be treated with 2% lidocaine jelly used as a lubricant and the examination can then continue. Moderate pain can be managed with the application of procedural sedation (Chapter 159). Severe pain associated with anal fissures or anal abscesses is best managed in the Operating Room under general anesthesia.

Strictures can occur from postsurgical changes, inflammatory bowel disease, chronic diarrhea, and other disease processes. Anoscopy should not be performed if the patient has anal strictures, a partially imperforate anus, a completely imperforate anus, or prolapsed thrombosed internal hemorrhoids. The Emergency Physician should determine if the anoscope will pass through the anus during the visual examination and the digital rectal examination. **Never insert the anoscope if resistance is encountered. The anoscope should not be used to dilate the anus.**

Anoscopy is contraindicated if major genitourinary trauma is sustained or in patients with an acute abdomen. It is also contraindicated

if any recent surgical procedure has been performed on the anus. The exception is for the physician who performed the surgical procedure. Anoscopy should be performed with caution in patients with prosthetics or valvular heart diseases requiring prophylactic antibiotics and those with coagulopathy or taking anticoagulants if biopsy is considered.

EQUIPMENT

- Water-soluble lubricant
- Lidocaine jelly, can be used as lubricant for patients with pain
- Anoscope or Vernon-David rectal speculum (**Figure 88-3**)
- Drapes
- Examination table, preferably a proctoscopy table
- Nonsterile examination gloves
- 4×4 gauze squares
- Large cotton-tipped applicators
- 4–0 chromic gut suture
- Suction, optional
- Bright directional light source
- Tincture of benzoin
- 2 inch adhesive tape

There are many different types of anoscopes available (**Figure 88-3**). The type of instrument chosen is largely the preference of the examining physician. The Vernon-David type anoscope is often preferred as it has a wide fenestration and a diameter that is not too large for most patients while allowing the best view (**Figure 88-3A**). The Ives (**Figure 88-3B**) or Hirschman (**Figure 88-3C**) anoscope may be used if a larger diameter instrument is required. There are disposable plastic anoscopes that are available and used in many Emergency Departments (**Figures 88-3D, 88-3E, and 88-3F**). Some of the metal reusable and plastic disposable anoscopes allow for the attachment of a fiberoptic light source. Many of these anoscopes are convenient but do not allow the same view as a Vernon-David anoscope. The AnoSpec (OPB Medical, Lawrence, MA) is disposable plastic with a built-in light source (**Figure 88-3F**). **Some physicians use a glass test tube as a substitute for an anoscope. Test tubes should not be used as they can break and cause serious complications.**

The anoscope is a two-piece device (**Figure 88-4**). It ranges from 7 to 25 cm in length. It can be manufactured from clear plastic, opaque plastic, or metal. The anoscope may have a handle that allows the operator to control its movements. The proximal end is funnel-like and tapers into the cylindrical shaft that is approximately 2.5 cm in diameter. The distal end of the anoscope is tapered on one side and known as the fenestration. The fenestration allows the mucosa to be viewed within the anoscope. It is also where procedures are performed through the anoscope. Some anoscopes have a site proximally to attach a light source. The obturator is smooth tipped, fits within the anoscope, and occludes the anoscope. Its rounded, distal end protrudes from the anoscope. The obturator is used each time the anoscope is inserted to prevent trauma to the anal mucosa. It is removed after the anoscope is inserted to allow viewing through the anoscope.

PATIENT PREPARATION

The area being examined is within the anal canal and requires no special preparation to view correctly. The patient should be given an opportunity to voluntarily evacuate their bowels prior to the

FIGURE 88-3. Some of the types of anoscopes available. **A.** Vernon-David anoscope. **B.** Ives anoscope. **C.** Hirschman anoscope. **D.** A disposable anoscope. **E.** Sani-Scope 2 anoscope. **F.** Various sizes of the AnoSpec. (Photo courtesy of OPB Medical.)

FIGURE 88-4. An example of an anoscope.

examination. It is necessary to have the patient remove their clothes from the waist down and provide barriers to protect the patient, the patient's clothing, and the surrounding area from spills. It is usually wise to avoid enema preparations as liquid stool is much more difficult to contain than solid stool.

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Explain to the patient what to expect. Discuss the order of the examination, the importance of relaxing, the reason for multiple insertions and withdrawals of the anoscope, and what you are looking for or expect to find. Obtain an informed consent for anoscopy and any procedures that may be performed.

Anoscopy can be performed with the patient in one of many positions.¹⁰ The position that allows the best observation in most patients is the knee-chest or prone position (**Figure 88-5**). This allows the buttocks to be to either side and places the anus at the proper angle. Examination of the anus in this position is easiest on a proctoscopy table but can be performed on an examination table or gurney. The lateral decubitus position with the knees drawn up and the buttocks

FIGURE 88-5. The knee-chest position.

protruding partly off the table is acceptable for limited diagnostic examinations. Large buttocks may prevent the examination. Apply tincture of benzoin to the buttocks and allow it to dry. Apply 2 inch adhesive tape to the buttocks and tape them to the examination table to spread the buttocks apart (**Figure 86-4**). Place a Mayo stand or bedside examination table next to the patient's buttocks.

Carefully inspect the entire perineum and anal verge. Many types of pathology such as fissures, fistulas, hemorrhoids, condylomata, and dermatologic conditions can be seen at this time. **A digital rectal examination with a well-lubricated gloved finger prior to anoscopy is mandatory.** The digital rectal examination has many advantages.¹ It allows one to find pathology that is better palpated than viewed. It gives the examiner the size and angle of the anal canal. It will allow the examiner to identify whether the patient has tenderness that would preclude anoscopy. Any strictures will be identified and allow the examiner to prevent the anoscope from advancing through these strictures and lacerating the tissues. It may identify pathology, so that the examiner can focus anoscopy in a specific area. It prelubricates the anal canal to make insertion of the anoscope easier. Lidocaine jelly can be used as a lubricant and as an anesthetic if the patient has pain from excoriation. The use of

intravenous analgesics, intravenous sedatives, procedural sedation, or general anesthesia may be occasionally required if the patient has significant pain.

TECHNIQUE

The technique of anoscopy is rather simple.⁹ Look closely at the anoscope and be sure it is intact and correctly assembled. Liberally lubricate the obturator and anoscope. Ensure that the obturator is easily removed and replaced from within the anoscope. Grasp the anoscope with the dominant hand and the obturator secured in place by the thumb of that hand (**Figure 88-6A**).

Use the nondominant hand to spread the anus (**Figure 88-6A**). Place the obturator at the center of the anus. **Slowly insert the anoscope and allow time for the internal anal sphincter muscle to relax.** Direct the tip of the obturator toward the patient's umbilicus (**Figure 88-6A**). Insert the anoscope to its fullest depth to start the examination with the area of fenestration pointed toward the area you wish to view first (**Figures 88-6B and 88-6C**). Slowly remove the obturator and place it on a Mayo stand or a bedside table where it can easily be retrieved. Adjust the directional light for the best illumination.

The usual starting place for the examination is the posterior midline (**Figures 88-6B and 88-6C**). Slowly withdraw the anoscope under direct observation to evaluate the entire depth of the anal canal exposed by the fenestration. Remove any fecal material with a cotton-tipped applicator. Note the appearance of the dentate line, the mucosa, and the anoderm. Note the presence and location of any blood, hemorrhoids, masses, mucus, purulence, or other abnormalities. A cotton-tipped applicator can be used to gently move the mucosa to view between the columns if the anoscope does not fully dilate the columns of mucosa. Continue to withdraw the anoscope as the mucosa is viewed.

Replace the obturator when the anoscope is fully removed from the patient. Rotate the anoscope 30° to 40° and reinsert it into the anal canal. It often takes four or five repeated insertions to evaluate the entire circumference of the anal canal. Some physicians prefer to replace the obturator and rotate the anoscope while it is still within the anal canal. This method is discouraged as it may pinch the tissue

FIGURE 88-6. Placement of the anoscope. **A.** The nondominant hand is used to spread the anus. The anoscope is inserted at an angle and aimed toward the umbilicus. Note that the dominant thumb is used to secure the obturator within the anoscope. The anoscope is completely inserted with the fenestration pointed toward the posterior midline (**B**) or the area of interest (**C**).

of the anus between the obturator and the viewing tube and does not allow the examiner to see the entire depth of the anal canal.

It is helpful to ask the patient to bear down when examining the left-lateral, right-posterior, and right-anterior sections of the anal canal when evaluating the internal hemorrhoids. It is often possible to reproduce the prolapsing of internal hemorrhoids to evaluate the grade of the hemorrhoids. Bearing down is particularly important if bleeding is the symptom. It is possible to identify the area of bleeding.

PEDIATRIC CONSIDERATIONS

Anoscopy may be performed in children for the same indications as an adult. An anoscope of 8 to 10 cm in length and 1 cm in diameter is appropriate for a neonate and young infant. An anoscope of over 12 cm in length and 1.5 cm in diameter is appropriate for an older infant and child. An adult anoscope is appropriate for an older child and adolescent. Disposable plastic laryngoscopes with a built-in light source (AnoSpec, OPB Medical, Lawrence, MA) are available in many Emergency Departments (**Figure 88-3F**). Position the young child supine with their buttocks at the edge of the examination table. Have an assistant grasp, abduct, and flex the child's thighs so they touch the abdomen without compressing the abdominal wall. The remainder of the procedure is as described above.

COMPLICATIONS

Examination of the anal canal with an anoscope should have minimal or no complications. It is possible to cause abrasions or lacerate the very thin anoderm. This is normally avoidable with adequate lubrication, the use of the obturator when inserting the anoscope, and a gentle technique. Minimal bleeding from mucosal irritation is common and self-limited. Dislodgement of a clot may result in hemorrhoidal bleeding that can be controlled with direct pressure, packing the anal canal with gauze squares, or a 4–0 chromic gut figure-of-eight suture. The most common complication is pain. This is avoidable by allowing enough time for the anus to relax while gently inserting the anoscope. The presence of an anal fissure may preclude the examination. The use of a topical anesthetic will usually allow the examination to proceed.

SUMMARY

Anoscopy is a commonly performed procedure in the Emergency Department. The anal canal is a cylindrical structure surrounded by sensitive anoderm and contracting anal sphincter muscles. The best way to examine this area is with a side-viewing fenestrated anoscope. Anoscopy allows direct viewing of the anal canal to best evaluate anal and perianal complaints. It will give the most information with minimal discomfort when properly performed. Always perform a digital rectal examination prior to anoscopy.

Rigid Rectosigmoidoscopy

Hao Wang, Nicole Remish, and Nestor Zenarosa

INTRODUCTION

Rigid rectosigmoidoscopy, although still widely used, has largely been replaced by the flexible sigmoidoscope for routine elective screening and diagnostic workups due to less patient comfort, relatively low diagnostic yield, and difficulty in performing associated procedures.¹ However, the rigid rectosigmoidoscope is superior to the flexible sigmoidoscope in measuring distances accurately, examining an unprepared patient, and working within the bowel lumen (e.g., when removing foreign bodies). The larger lumen of the rigid rectosigmoidoscope allows for a larger biopsy where pathology is in question. The cost associated with this examination is less than that for flexible sigmoidoscopy. The rigid rectosigmoidoscope can be purchased in a disposable model that performs well. It is important for the Emergency Physician who evaluates and treats problems related to the colon, rectum, and anus to be familiar with rigid rectosigmoidoscopy.

ANATOMY AND PATHOPHYSIOLOGY

The detailed anatomy of the anal canal is covered in Chapter 88. The gross anatomy of the colon is reviewed in **Figure 89-1A**. It is important to be aware of the large folds that impinge on the lumen of the colon called the valves of Houston (**Figure 89-1B**). These folds must be gently flattened to advance the rigid rectosigmoidoscope and clearly see the proximal side of the valve when looking for pathology. It is also necessary to understand the three-dimensional path followed by the distal colon, rectum, and anus. The direction to follow will be toward the patient's umbilicus for 3 to 5 cm initially. The anus then turns posteriorly as it becomes the rectum and follows the curve of the sacrum. The rectosigmoid junction is reached at 10 to 15 cm where the lumen sharply angulates anteriorly and to the left. Because the scope is rigid and straight, it is necessary to angle the tip of the rigid rectosigmoidoscope toward the lumen of the bowel and then gently flatten the haustra or move the patient's colon so that the lumen is in a straight line.

INDICATIONS

Many of the indications for rigid rectosigmoidoscopy are the same as those for performing flexible sigmoidoscopy. The rigid scope, however, is superior when the bowel is not properly prepared, if a bigger biopsy is needed, or if a larger instrument needs to be passed to the last 25 cm of the colon.

The rigid rectosigmoidoscope may be used to evaluate the rectum and sigmoid colon in the office or the Emergency Department. It can be used diagnostically to evaluate symptoms such as rectal bleeding, constipation, and diarrhea. Rectal bleeding can be evaluated in the unprepared patient. Rigid rectosigmoidoscopy is particularly helpful to determine if stool is mixed with blood when evaluating hematochezia and for determining whether colonoscopy is indicated. It provides diagnostic value when performing a biopsy or cytology of

FIGURE 89-1. Anatomy of the colon. **A.** The gross anatomy. **B.** Cross-section through the colon demonstrating the valves of Houston.

lesions within reach of the instrument. It can be used to accurately measure the distance to rectal lesions from the anus prior to surgery. It is also used for surveillance of colon or rectal cancer after a subtotal colectomy. As neoadjuvant treatments for rectal cancers significantly differ depending on the position and location of the tumor, rigid rectosigmoidoscopy can be used for identifying tumor burden locations. Current specific treatment is based on measurement standards.² The rigid rectosigmoidoscope is superior for traumatic injuries. The rectum is seldom prepared in the evaluation of a traumatic injury and flexible instruments are unable to clear solid or thick stool. Rigid sigmoidoscopy has also been shown to be superior to digital rectal examination alone in identifying penetrating rectal trauma. Rigid sigmoidoscopy had a sensitivity of 78% in diagnosing trauma compared to a sensitivity of 51% with digital rectal examination.³ Rigid rectosigmoidoscopy can also be used therapeutically. Foreign bodies in the rectum or sigmoid colon can be removed with grasping forceps through the scope. The rigid rectosigmoidoscope allows for larger biopsy specimens. Electrocoagulation of bleeding points or electrofulguration of small lesions can be performed during this procedure. A sigmoid volvulus can be decompressed using the rigid rectosigmoidoscope to pass a tube to splint the volvulus. It is much easier to suction out a large volume of obstructed material in the colon and leave a large tube with the rigid rectosigmoidoscope.

CONTRAINDICATIONS

Absolute contraindications are the same as those for anoscopy, which is reviewed in Chapter 88. Relative contraindications include an uncooperative patient, severe anal pain that may require general anesthesia, recent surgical anastomosis in the distal 25 cm of the colon and rectum, severe stenosis of the anus or rectum, and

peritonitis. Rigid rectosigmoidoscopy should be performed with great caution in patients with severe coagulopathy or patients requiring prophylactic antibiotics (e.g., neutropenia, endocarditis, valvular heart disease, or prosthetics) since the risk of bacteremia is high. This procedure should not be performed by anyone unfamiliar with the equipment and technique as significant complications can occur.

EQUIPMENT

- Phosphate soda enemas
- Rigid rectosigmoidoscope with obturator, air insufflator, eyepiece, and light source
- Suction catheter
- Suction machine or wall suction
- Biopsy forceps
- Long cotton-tipped applicator with a silver nitrate applicator on the opposite end
- Proctoscopy table or examination table
- Protective drape with exam fenestration
- 4×4 gauze squares
- Water-soluble lubricant
- Exam gloves
- Impermeable gown
- Instrument stand
- Anoscope should be available to examine the anal canal if indicated

The rigid rectosigmoidoscope and other required instruments are available in preassembled sterile trays. The tray usually contains the

FIGURE 89-2. The instruments required to perform rigid rectosigmoidoscopy. **A.** Obturator. **B.** Rigid rectosigmoidoscope. **C.** Suction catheter. **D.** Polypectomy snare. **E.** Biopsy forceps. **F.** Cotton-tipped applicator with silver nitrate matchstick taped to the opposite side.

rigid scope, an obturator, a suction catheter, polypectomy snare, and biopsy forceps (**Figure 89-2**). These trays are available from the Operating Room, hospital central supply, or the surgical clinics. The trays may contain disposable single-use instruments or multiuse instruments depending on the institution. The disposable equipment eliminates the risk of cross-contamination.⁴ The remainder of the equipment must be gathered from around the Emergency Department.

The rigid rectosigmoidoscope is a simple instrument (**Figures 89-2A and 89-2B**). The shaft is approximately 30 to 40 cm in length and has 1 cm increments marked on the outside. Attached to the proximal end are an eyepiece, a handle, and an inflation port. The eyepiece swings to open and close over the proximal shaft of the scope. The handle is used to direct and move the scope. Inside the handle is a fiberoptic light source that transmits into the shaft. The insufflator bulb and tubing attach to the inflation port. These are used to insufflate air through the scope and into the colon. The obturator fits within the shaft of the scope. The distal end of the obturator is smooth, occludes the shaft of the scope, and projects 1 to 2 cm distal to the scope.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. It is also important to explain to the patient what to expect. Discuss the order of examination, the importance of relaxing, the reason for multiple insertions and withdrawals of the rigid rectosigmoidoscope, and what you expect to find. It is important to explain the reason for insufflating air and how this may produce discomfort. Explain that the procedure should not require procedural sedation and that the patient should inform the Emergency Physician of any discomfort. Assure

the patient that the complaint of pain will at least temporarily stop the examination. Perforations are unlikely with a relaxed and cooperative patient. Obtain a signed informed consent for this procedure.

While it is possible to perform an examination with rigid rectosigmoidoscopy on an unprepared rectum, more information about the mucosa will be obtained if the bowel has been prepared. Two 4-ounce phosphate soda enemas given at 2 hours and 1 hour before the examination will provide adequate preparation in most patients. The use of high-volume polyethylene glycol (PEG) preparations, saline, or mannitol should be reserved for colonoscopy. There is no need to clean the entire colon. The preparations used for colonoscopy are expensive, involve too much preparation, and cause patient discomfort for the extent of the examination. The judicious use of intravenous sedation may be required in some patients who are anxious.

It is important to check the equipment prior to insertion into the patient. Open the tray and place the instruments and supplies on the Mayo stand. The eyepiece on the proximal end of the scope should open easily, close easily, and seal against the rigid rectosigmoidoscope. Open the eyepiece and insert the obturator completely within the rigid rectosigmoidoscope. The handle, including the light source, must be firmly attached. Turn on the light source. The light must be seen coming from the end of the scope. The bulb of the insufflator must pump air into the rigid rectosigmoidoscope and should reinflate after the bulb is released. Liberally lubricate the distal 5 cm of the rigid rectosigmoidoscope and the obturator. Reinsert the obturator into the rigid rectosigmoidoscope.

Disrobe the patient from the waist down. Place the patient in the prone jackknife (i.e., knee-to-chest) position on a proctoscopy table if one is available (**Figure 89-3A**). Examination in this position is relatively easy and less air inflation is required during the procedure, thus reducing patient discomfort. If the patient is unable to assume this position, or only a routine examination table or stretcher is available, place the patient in the left lateral decubitus or Sims position (**Figure 89-3B**). Examination in this position requires some experience and is not recommended for novices. The Emergency Physician should be prepared with an impermeable gown and one glove on the left hand and two on the right hand (if right handed). It is helpful to have someone assist with the remainder of this procedure. Place the fenestrated drape over the patient so that the buttocks are completely exposed (**Figure 89-3**). Place a Mayo stand or bedside procedure table within reach of the patient's buttocks.

As in anoscopy, it is important to carefully inspect the entire perineum and anal verge prior to the examination. Many types of pathology such as fissures, fistulas, hemorrhoids, condylomata, and dermatologic conditions may be seen at this time.

Digital rectal examination with a well-lubricated, gloved finger is mandatory prior to rigid rectosigmoidoscopy. This step allows the examiner to find pathology that is better palpated than viewed and allows greater focus on a specific area. It will also allow the examiner to evaluate the size and angle of the anal canal, assess for patient sensitivity or tenderness prior to rectosigmoidoscopy, and prelubricate the anal canal making insertion of the rigid rectosigmoidoscope easier. Use 2% lidocaine jelly as a lubricant and to provide some local anesthesia if the patient has pain from excoriation. This examination is usually performed with the right hand. Remove the extra glove from the dominant hand before picking up the rigid sigmoidoscope. This prevents the contaminated glove from holding the scope near the Emergency Physician's face.

TECHNIQUE

Stand to the left side of or directly behind the patient. Place the left, or nondominant, hand on the patient's buttocks (**Figure 89-4A**). Grasp the handle of the rigid rectosigmoidoscope with the right,

FIGURE 89-3. Patient positioning. **A.** The prone jackknife position on a proctoscopy table. **B.** The left lateral decubitus position on an examination table with the buttocks extended over the edge of the table. Note that the drape is placed so that the buttocks are completely exposed.

FIGURE 89-4. Insertion of the rigid rectosigmoidoscope. **A.** The left (nondominant) hand is placed on the buttocks and used to spread the buttocks. **B.** The right (dominant) hand is used to insert and advance the scope while the thumb keeps the obturator properly seated.

or dominant, hand. Place the right thumb on the obturator to keep it properly seated (**Figure 89-4B**). Spread the buttocks with the left hand (**Figure 89-4**). Gently and slowly insert the rigid rectosigmoidoscope into the anus and aimed toward the patient's umbilicus. Advance the scope to the 5 cm mark.

Support the rigid rectosigmoidoscope at the anus with the left hand (**Figure 89-5A**). This is necessary so that if the patient moves, the instrument will move with the patient. Remove the obturator and place it on the Mayo stand. Close the eyepiece and insufflate air into the rectum.

One must control the insertion and direction of the rigid rectosigmoidoscope with the right hand while stabilizing it with the left hand (**Figure 89-5A**). Continue to slowly advance the rigid rectosigmoidoscope under direct viewing while simultaneously insufflating air to distend the walls of the colon (**Figure 89-5A**). The anal canal is approximately 4 to 5 cm in length (**Figure 89-6**). The rectum will be seen to turn somewhat posteriorly and follow the hollow of the sacrum (**Figure 89-5B**). Moving the right hand and the rigid rectosigmoidoscope anteriorly will direct the tip posteriorly (**Figure 89-6B**). Use the left hand as a fulcrum to help maneuver the distal tip of the rigid rectosigmoidoscope to follow the lumen of the rectum (**Figure 89-6**). The sigmoid colon can also be identified by the presence of transverse folds that are lacking in the rectum. The rectosigmoid junction is approximately 16 cm from the anus and can be seen when the lumen turns anteriorly and to the right (**Figure 89-6C**). It is necessary to use the rigid rectosigmoidoscope to gently straighten the colon while completely inserting the instrument to a depth of 25 cm. **It is important to view the bowel lumen at all times. Never advance the instrument blindly as this may cause a perforation.**

Maintain communication with the patient, inform them of what is happening, and ensure patient comfort throughout the procedure. Open the eyepiece if it becomes clouded with moisture and wipe it with dry gauze so the view is kept clear. **Do not keep your face near the eyepiece when opening the eyepiece.** The insufflated air may forcefully expel stool and secretions.⁵ The bowel must be reinflated when the eyepiece is reclosed.

After the rigid rectosigmoidoscope is advanced to 25 cm, or as far as the patient will allow, slowly remove it with a circular motion (**Figure 89-7**). View the mucosa while removing the rigid rectosigmoidoscope in a circular motion. This flattens out the haustra and valves of Houston so that the entire mucosal surface can be viewed.

FIGURE 89-5. Advancement of the rigid rectosigmoidoscope. **A.** The nondominant hand stabilizes the scope while the dominant hand advances it under direct visualization. **B.** The rectum begins as the anal canal turns posteriorly toward the sacrum.

Attempt to keep at least 50% of the colonic lumen in view at all times. Open the eyepiece just prior to completely removing the rigid rectosigmoidoscope to release as much of the insufflated air as possible. This will make the patient more comfortable.

The viewing window, which seals in the air, must be opened if it is necessary to biopsy or to grasp something. This will result in the collapse of the rectum and loss of view. It is important to place the tip of the rigid rectosigmoidoscope over the area in question so it will

stay in the examiner's view. The obturator should be reinserted if it is necessary to reinsert or readvance the rigid rectosigmoidoscope.

ASSESSMENT

Completely and carefully inspect the colonic mucosa. Note the presence, location (i.e., anterior, posterior, left, right), and depth of any bleeding, diverticula, fistulas, hemorrhoids, lesions, masses,

FIGURE 89-6. Insertion and advancement of the rigid rectosigmoidoscope. **A.** The scope is inserted and aimed toward the umbilicus. **B.** Moving the handle anteriorly will direct the tip of the scope posteriorly. **C.** The rectosigmoid junction is located approximately 16 cm from the anus, where the rectal lumen turns anteriorly and to the right.

FIGURE 89-7. The rigid rectosigmoidoscope is rotated in a circular motion while simultaneously withdrawing the scope and visualizing the mucosa.

mucosal irregularities, and/or polyps. Document any of these findings in the medical record.

AFTERCARE

The patient may be discharged home after the procedure if there are no complications and there is no other reason to admit them to the hospital. They may experience mild discomfort, flatus, and spotting of blood in the stool for several hours. Instruct the patient to immediately return to the Emergency Department if they develop a fever, abdominal pain, nausea, vomiting, bright red blood per rectum, or if they have any concerns. Follow-up should be arranged with a Family Practitioner, Internist, Gastroenterologist, or Surgeon depending on the findings of the examination.

COMPLICATIONS

The primary complication of rigid rectosigmoidoscopy is perforation of the rectum or sigmoid colon. Air insufflation may cause an existing perforation (e.g., one associated with diverticulitis) to burst and is the reason to not perform this examination if the patient has existing peritonitis. Perforation can occur with forceful insertion of the instrument without viewing the colonic lumen or if the patient moves suddenly and the scope is not supported properly. Perforation may also occur with instrumentation in related procedures (e.g., a biopsy). The risk of perforation greatly decreases when performed with proper technique, maintaining visualization of the colonic lumen while advancing the scope, and responding appropriately to the patient's complaints of pain.

Minor complications may occur. Trauma to the mucosa from the rigid rectosigmoidoscope or instrumentation from related procedures (e.g., a biopsy) can result in minor bleeding that is usually self-limited. Brisk bleeding can be controlled by the judicious use of a silver nitrate matchstick. Bacteremia may occur in up to 10% of patients. Administer antibiotic prophylaxis for high-risk patients prior to the procedure. Mild abdominal discomfort and flatus can last a few hours.

The light source can fail suddenly. This causes problems for both the Emergency Physician and the patient. There is no need to discontinue or postpone the rigid rectosigmoidoscopy. Attach a penlight to the rigid rectosigmoidoscope and continue the examination.⁶

SUMMARY

Rigid rectosigmoidoscopy is inexpensive, easy to perform, and useful in visual examination of bowels with poor preparation and/or where wider access is needed. These characteristics make the instrument useful in many situations. The proper training and understanding of the anatomy of the region is imperative. This examination is well tolerated by the patient and is useful in diagnosing and treating many colonic and rectal problems.

Rectal Foreign Body Extraction

Chad Holmes, Jon Wolfshohl, and Hao Wang

INTRODUCTION

Foreign bodies within the rectum are the result of an ingestion or placed into the anus.¹ Fortunately, the majority of items ingested orally that pass the pylorus and ileocecal valve also pass the anal sphincter. The most frequent types of items found in the anus from ingestion are undigested fish or chicken bones.² Foreign bodies that are placed into the rectum are placed iatrogenically (e.g., enema tips and thermometers), inserted by the patient in an attempt to remove impacted stool, inserted by the patient or their partner as a form of sexual gratification, forcibly placed in the anus during a rape, or placed in the rectum as a means of concealment (i.e., body packing and body stuffing).²⁻⁴

The items placed into the rectum from the anus seem to be limitless and represent all shapes and sizes imaginable.⁵ This makes their removal more difficult. **It is important to attempt to identify the characteristics of the foreign body to devise the safest method of removal.** As an example, consider the typical electric lightbulb. The glue that attaches the metal base to the glass loosens with moisture and time. Pulling off the metal base exposes a thin, sharp glass edge. The glass globe is thin and breaks very easily. If the glass breaks, it may take a long time to remove the fragments and cause considerable damage to the surrounding rectal mucosa or the examining finger. **The idea is to remove the foreign body without causing further damage to the rectum or the anal sphincter muscle.** The more knowledge the Emergency Physician has about the foreign body and how it was inserted, the more likely it is that it will be removed safely.^{6,7}

ANATOMY AND PATHOPHYSIOLOGY

The significant anatomy of the anal canal is discussed in Chapter 88. An important anatomic consideration in removing rectal foreign bodies include the axis of the lumen of the anus. The anus is pointed toward the patient's umbilicus, while the curve of the sacrum forms a posterior arc. If the length of the foreign body is longer than the curve of the sacrum (e.g., a long vibrator or dildo), the sacral promontory causes the distal end of the foreign body to be directed toward the tip of the sacrum or coccyx. When the object is being removed by bringing the distal end anteriorly, the middle portion may push anteriorly (i.e., into the prostate, uterus, or bladder) and cause considerable discomfort.

The important physiologic considerations include the anal sphincter muscles, edema, and the creation of a vacuum. The anal sphincter is a complex group of muscles. The external anal sphincter muscle is made up of voluntary muscle fibers. The internal anal sphincter muscle is made of smooth muscle fibers. The reflex response to dilatation of the rectum is contraction of the external anal sphincter muscle. The normal tone of the anal sphincter comes from the internal anal sphincter and can go into spasm with manipulation.

Therefore, it is very important to try to remove foreign bodies with slow and steady traction. Maintain constant pressure and wait for the sphincter muscle to fatigue. The technique is not too dissimilar to the methods used to relocate a shoulder. The slow and constant traction will also help with the edema that forms around rectal foreign bodies that have remained in the rectum for a prolonged period.

It is important to consider the formation of a vacuum that may result from traction on a large and/or smooth foreign body (e.g., a bottle or lightbulb). It is sometimes necessary to place one or more soft catheters above the foreign body so that air may get around the object as it is removed. This will prevent the formation of a vacuum and allow the foreign body to be removed. Large Foley catheters with the balloon

inflated can be used for air insertion to prevent the vacuum and traction on it can bring the object further down into the rectum.

INDICATIONS

The indication to remove a foreign body from the rectum is the identification of a foreign body in the rectum. The majority of patients presenting with a rectal foreign body have attempted to remove the object prior to arrival. Common efforts to remove these objects at home include expulsion by bowel movement or oral laxatives.⁸ It is impossible to estimate the number of rectal foreign bodies that are removed at home. It is estimated that very few objects inserted

through the anus will pass spontaneously. Delaying extraction is detrimental for the vast majority of rectal foreign bodies. Sharp objects may already have begun to perforate the rectum. Large foreign bodies will continue to cause irritation and edema, making removal more difficult with the passage of time. An algorithm for rectal foreign body removal is provided in **Figure 90-1**.

CONTRAINDICATIONS

There are a few absolute contraindications to removing a rectal foreign body in the Emergency Department. **The removal of a rectal foreign body that has not perforated is not an emergency.** Time

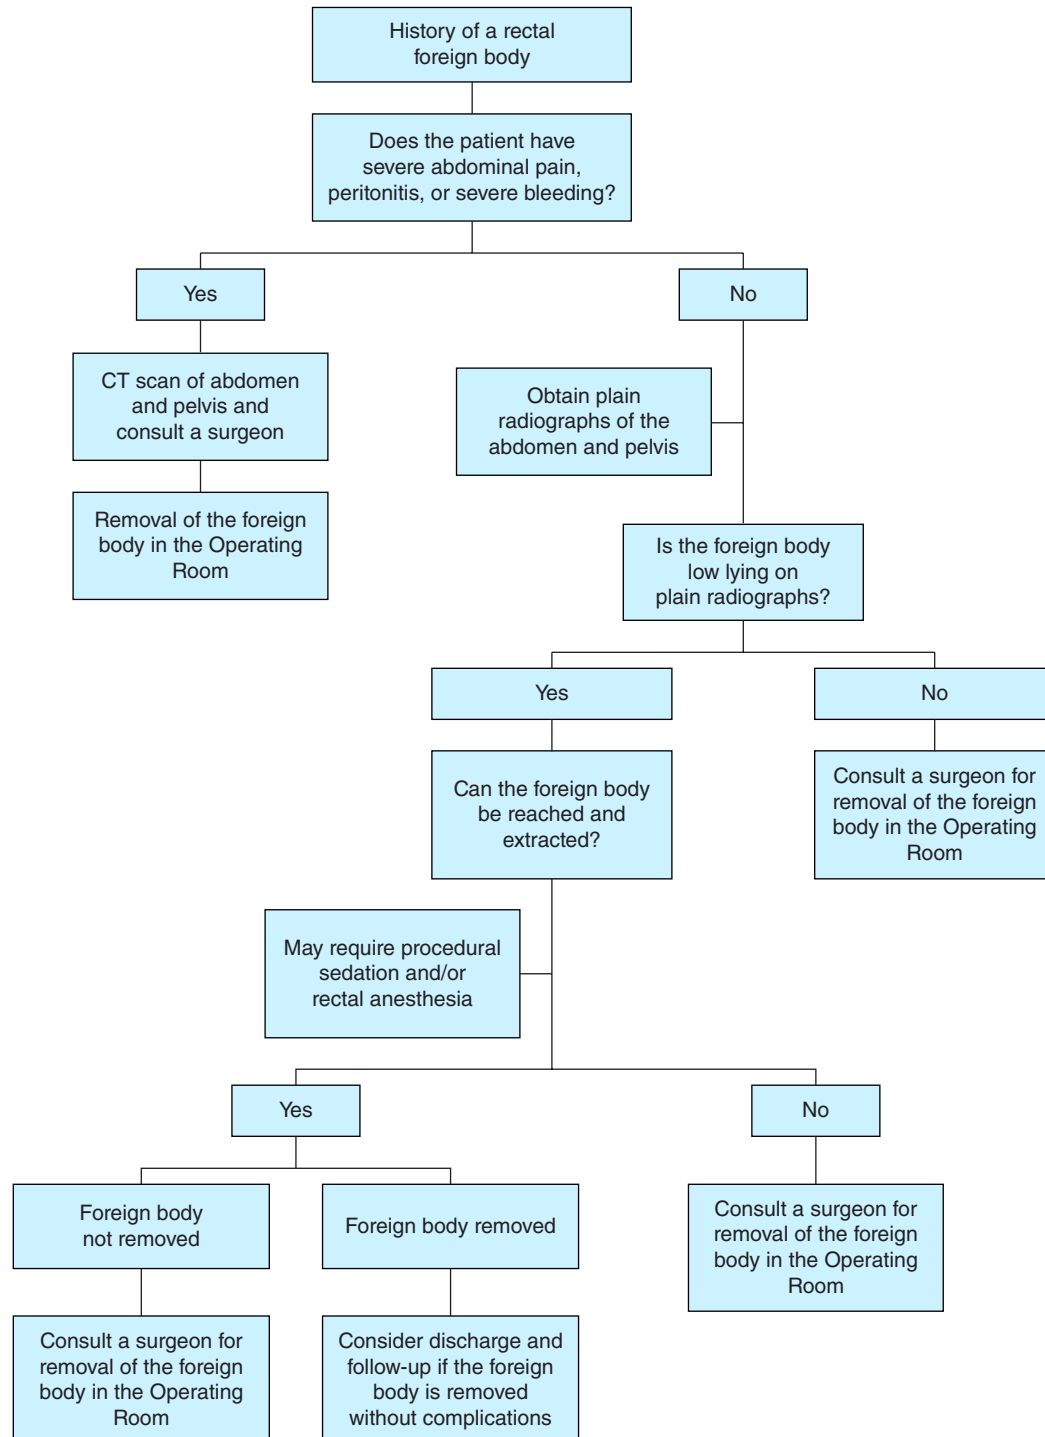

FIGURE 90-1. An algorithm for the management of a rectal foreign body. CT, computed tomography.

should be taken to plan the extraction and achieve adequate anesthesia and relaxation of the anal sphincter muscles, especially if the object is difficult to retrieve. The patient's general condition must be considered. Patients with peritonitis require operative removal and exploration.⁹ The time taken to remove the object is wasted and identification of the perforation is easier in the Operating Room with the item in place. Patients with lower abdominal pain and fever may have a perforation in the extraperitoneal space that can be confirmed with a water-soluble contrast enema. Foreign bodies that are large, irregularly shaped, or have sharp edges should be extracted in the Operating Room. **A complete assessment of all the patient's injuries is mandatory in patients who have been assaulted.** It is usually better to leave the object in place to help identify any associated injuries. The foreign body should be removed in the Operating Room if it is not palpable, it is not visible upon dilating the anus, or removal of the object may cause injury to the patient. Packets containing illicit drugs should be extracted with a rigid rectosigmoidoscope or in the Operating Room. Rupture of the packets can result in significant morbidity and mortality.

EQUIPMENT

- Local anesthetic solution with epinephrine (e.g., 1% lidocaine or 0.5% bupivacaine)
- 25 gauge needle, 2 inches long
- 10 mL syringe
- Povidone iodine or chlorhexidine solution
- Anoscope
- Ring forceps
- Tenaculum
- Park retractor
- Hill-Ferguson retractor
- Large spoons
- Foley catheters
- Endotracheal tubes
- Endoscopic snare
- Rigid rectosigmoidoscope
- Vacuum extractor, optional

PATIENT PREPARATION

The patient must undergo a complete history and physical examination.^{3,10,11} It is important to ascertain the overall health of the patient in case it is necessary to go to the Operating Room to extract the foreign body. **Attempt to identify patients with peritonitis or rectal perforations because they need to go to Operating Room immediately.**⁹ Biplane upright plain radiographs are useful to determine the number, shape, and location of foreign bodies as well as the presence of free air under the diaphragm. It is necessary to look at both the anteroposterior view as well as the lateral view to completely appreciate the object in three dimensions.¹ It is important to inform the patient in advance that while 90% of the objects can be removed from below, some may require general anesthesia or even an operation and a temporary colostomy. Explain the risks, benefits, and complications of the local anesthesia and the extraction procedure to the patient and/or their representative. Obtain an informed consent for the extraction of the foreign body and the method of anesthesia.

Ascertain the type and number of objects in the rectum.¹² It is possible to remove one foreign body and miss others that the

Emergency Physician was not aware were present. It is common to find that the patient is unsure of this part of the history. Plain radiographs can be helpful.^{8,13} It is also important to identify the technique of insertion. **Patients with objects that were inserted forcefully should undergo a trauma-oriented workup, and sexual abuse must be considered.** Determine the length of time since insertion. Edema formation will be significant if the object has been present more than 24 hours. This will make it more likely that an anesthetic will be needed or that it will be necessary to use catheters to break the vacuum that forms during the extraction.

The parts of the physical examination that are most helpful are the abdominal and rectal examinations. The abdominal examination should focus on the presence or absence of tenderness, peritonitis, and the palpation of a mass. Some objects are long enough to be palpated in the left lower quadrant. It may be useful to apply pressure on the lower portion of the abdomen to help remove the object. The rectal examination should include a careful external examination looking for evidence of tissue bleeding or other forms of trauma. The digital portion of the examination can roughly evaluate sphincter tone and squeeze pressure.

The remainder of the examination should consist of careful palpation of the foreign body to determine its location, tensile strength, texture, mobility, and to identify possible areas to grasp. Examples would include the open end of a bottle or the narrow end of a light-bulb. Determining if the object is hard, soft rubber, or plastic will help to determine the tool best suited to grasp the object. One contraindication to performing the digital rectal examination would be determining, on radiographs or by history, whether the object is sharp (e.g., a knife blade) or consists of broken glass. **It is recommended to postpone the digital rectal examination, especially in prisoners and psychiatric patients, until radiographs rule out a sharp foreign body.** If the examiner is not able to palpate the foreign body, a rigid rectosigmoidoscope should be used to identify and remove the object. The technique of rigid rectosigmoidoscopy is described in Chapter 89.

ANESTHESIA

The second general consideration is the patient's comfort level during the procedure. Several methods can be used to relax the patient and reduce anal sphincter spasms.¹² The use of intravenous or procedural sedation (Chapter 159) will relax the patient and relieve much of the discomfort associated with the procedure. It may be necessary to inject the anus with local anesthetic solution if the patient experiences pain or if slow steady traction will not overcome the tone of the anal sphincter.^{14,15} Anesthesia of the sphincter muscles will provide for patient comfort and allow dilation of the sphincter muscles. Place the patient in the lithotomy position (**Figure 90-2A**). Wipe away any dirt, debris, and fecal material from the perianal skin and surrounding area. Apply povidone iodine or chlorhexidine solution and allow it to dry. Inject local anesthetic solution subcutaneously and circumferentially around the anus (**Figure 90-2A**). Inject 1 to 1.5 mL of local anesthetic solution into the anal sphincter muscles at the 12, 3, 6, and 9 o'clock positions (**Figure 90-2B**).

An alternative is a pudendal nerve block. Determine if the ischial spines are palpable through the rectum. Insert the needle through the skin and toward the ischial spine. Use the finger inside the rectum to palpate and guide the needle to the ischial spine. Inject 3 to 5 mL of local anesthetic solution just medial to the ischial spine. Repeat this procedure on the other side. **The main disadvantage of the pudendal nerve block is that it is a blind procedure and has the potential for a needle-stick.** It will be necessary to take the patient to the Operating Room for regional or general anesthesia if procedural sedation or a pudendal nerve block is not successful.

FIGURE 90-2. Anesthesia of the anal region. **A.** Local anesthetic solution is infiltrated subcutaneously and circumferentially around the anus. **B.** Injection of local anesthetic solution into the anal sphincter muscles.

The patient may remain in the lithotomy position for the extraction of the foreign body (**Figure 90-3A**). Other positions include the modified Lloyd Davies position (**Figure 90-3B**) and the Sims position (**Figure 90-3C**). The choice of positions is physician dependent and limited by patient comfort.

TECHNIQUES

It is important to understand that the types of foreign bodies found in the rectum are variable. It is impossible to give exact instructions on how to remove them. There are some general considerations to remember. The first is to try to visualize the foreign body. Gentle suprapubic pressure will often push the foreign body into the distal rectum. The distal end of the foreign body may get caught along the curve of the sacrum. Place a finger in the rectum to redirect the orientation of the foreign body. The second consideration is to grasp the object. Sometimes an object is low-lying and may be grasped with gloved fingers.¹² The object can then be removed by gentle continuous traction. Low-lying objects may be soft enough to be grasped with an instrument. **It is necessary to do this under direct vision so that the rectum will not be damaged in the attempt to grasp the foreign body.** Hard, low-lying objects made of metal or plastic may be grasped with a tenaculum.

Insert two well-lubricated fingers into the anesthetized anus and gently dilate the anal sphincter muscles. The anus can be maintained in the open position by the insertion of a Park retractor (**Figure 90-4A**) or a Hill-Ferguson retractor (**Figure 90-4B**). An anoscope or vaginal speculum may be used if these retractors are not readily available in the Emergency Department. View the distal end of the foreign body. **Never insert instruments unless the foreign body is visualized. Blind insertion of instruments may push the foreign body more proximally or perforate the rectum. Never grasp a foreign body blindly. This can cause injury to the rectum upon removal of the instrument if the rectal mucosa is entrapped between the instrument and the foreign body.**

DIGITAL EXTRACTION TECHNIQUE

Foreign bodies within reach may be grasped with the fingers and extracted. This often proves very difficult as the foreign body will be coated with lubricant, mucus, and/or stool. Instruct the patient to bear down as if having a bowel movement. The intraabdominal

pressure generated in this way may expel the foreign body. The foreign body may become entrapped against the sacrum. Insert a finger into the rectum to dislodge the foreign body from against the sacrum as the patient continues to bear down. Attempt one of the techniques described below if digital extraction is ineffective.

FOLEY CATHETER TECHNIQUE

A Foley catheter has been successfully used to aid in the extraction of rectal foreign bodies.^{2,16-20} This is especially helpful if the foreign body is large, made of glass, an inverted bottle or can, or has been retained for more than 12 to 24 hours. Pulling these types of foreign bodies can result in the formation of a vacuum proximally and inhibit their extraction. It is sometimes necessary to place one or more soft catheters above the foreign body so that air may get around the object as it is removed to prevent the formation of a vacuum.

Liberally lubricate a Foley catheter. Insert the Foley catheter between the foreign body and the rectal mucosa. Advance the catheter until the balloon is proximal to the foreign body (**Figure 90-5A**). Fluoroscopy, if available, can be used to confirm the location of the balloon and guide the removal of the foreign body.²¹ Inflate the balloon with 30 mL of saline or water. Inject air with a syringe through the Foley catheter to break the vacuum proximal to the foreign body. Remove the syringe so that air can move freely through the Foley catheter and prevent a vacuum from becoming reestablished. Apply constant, gentle, and steady traction to the Foley catheter. This will prevent the foreign body from migrating proximally. It may also move the foreign body distally so that it can be grasped and extracted with fingers or an instrument. The use of two to four circumferentially placed Foley catheters may apply evenly distributed traction to extract the foreign body more easily.

ENDOTRACHEAL TUBE TECHNIQUE

An endotracheal tube has been used in place of a Foley catheter by some physicians (**Figure 90-5B**). The advantage of using an endotracheal tube is that it is relatively stiff and can apply more traction than a Foley catheter to help remove the foreign body. Unfortunately, there are also disadvantages. The endotracheal tube is larger and less flexible than a Foley catheter. This may result in difficulty advancing it past the foreign body. The larger and stiffer endotracheal tube can more easily lacerate the rectal mucosa and perforate

FIGURE 90-3. Patient positioning for removal of rectal foreign bodies. **A.** Lithotomy position. **B.** Modified Lloyd Davies position. **C.** Sims or lateral decubitus position.

the rectum. **For these reasons, the use of an endotracheal tube cannot be recommended.**

SPOON TECHNIQUE

The removal of smooth, round, fragile, or glass foreign bodies can be problematic. This can include lightbulbs, balls, fruits, and vegetables. These foreign bodies can be extracted with a pair of large spoons. Liberally lubricate the posterior surface of a pair of spoons. Insert a Foley catheter to eliminate the vacuum proximal to the foreign body. Insert the spoons until they are cupping the foreign body (**Figure 90-5C**). Grasp and gently squeeze the handles of the spoons so that they hold the foreign body. Withdraw the spoons and the foreign body.

A more readily available alternative to large spoons are obstetric forceps.²² These have also been successfully used to extract a rectal foreign body. **The use of obstetric forceps cannot be recommended**

due to their large size, unfamiliarity to most Emergency Physicians, and the potential to perforate the rectum.

RING FORCEPS OR TENACULUM TECHNIQUE

Rectal foreign bodies that are not fragile may be grasped with a ring forceps or tenaculum and then extracted.^{23,24} Insert a Foley catheter to eliminate the vacuum proximal to the foreign body. Firmly grasp the foreign body with a ring forceps or a tenaculum (**Figure 90-5D**). A tenaculum has teeth on its distal tips. These may be advantageous as the teeth can grip and firmly hold the foreign body to make the extraction easier. **This must be performed under direct visualization to ensure that the rectal mucosa is not entrapped between the instrument and the foreign body.** Apply gentle and firm traction to extract the foreign body.

VACUUM EXTRACTION TECHNIQUE

A vacuum dart or obstetrical vacuum extractor may be used to extract a rectal foreign body.^{17,25,26} Emergency Physicians are usually not trained in the proper use of a vacuum extraction device. It may be beneficial to have an Obstetrician, Gynecologist, Family Practitioner with obstetric experience, or a Nurse Midwife to assist with this technique.

Insert a Foley catheter to eliminate the vacuum proximal to the foreign body. Place the vacuum cup of the device onto the foreign body. **Ensure that none of the rectal mucosa is entrapped between the rim of the suction cup and the foreign body.** Apply the suction to seal the cup against the foreign body. **Recheck to ensure that none of the rectal mucosa has become entrapped.** Apply steady traction to extract the foreign body.

MISCELLANEOUS TECHNIQUES

Numerous other techniques have been devised to remove a rectal foreign body.²⁷⁻³¹ These include the use of proctoscopes and snares, Magill forceps (**Figure 18-16A**), Boedeker forceps (**Figure 18-16B**), Tylke forceps (**Figure 18-16C**), de Pezzer catheters, cyanoacrylate glue, clamps covered with rubber tubing, a tonsil snare, Sengstaken-Blakemore tubes, and plaster of Paris. Cyanoacrylate glue can be used to attach a handle to the foreign body. The foreign body can be extracted by withdrawing the handle after the glue has dried. A Sengstaken-Blakemore tube can be inserted into a foreign body with a small opening (e.g., glass bottle, soda can). Inflate the balloons and apply traction to extract the foreign body. Plaster of Paris can be used to fill a hollow object and allowed to harden around a tongue blade (**Figure 90-5E**). This is analogous to making a popsicle on a stick. The major disadvantage of using plaster of Paris is that it generates heat as it hardens. This heat may damage the rectal mucosa or shatter a glass bottle. The technique of rectal foreign body extraction is limited only by one's level of experience, comfort with the procedure, and available resources.³²

ASSESSMENT

Examine the rectum with a rigid rectosigmoidoscope to assess the mucosa for tears or perforations after the foreign body is extracted. Some physicians believe that this examination is not necessary if the patient is asymptomatic, the foreign body is smooth, the foreign body was extracted atraumatically, and no complications arose from the extraction procedure. These patients may be discharged with follow-up as an outpatient for rectosigmoidoscopy. The patient should remain in the hospital for observation and consultation with a General or Colorectal Surgeon if there is damage to the rectal or anal mucosa. The patient should remain NPO and be prepared for

FIGURE 90-4. Retractors placed in the anus allow for better exposure and easier extraction of the foreign body. **A.** The Park retractor. **B.** The Hill-Ferguson retractor.

possible surgery. Other indications for admissions include abdominal pain, significant bleeding, or the suspicion of a bowel or rectal perforation. Broad-spectrum intravenous antibiotics should be administered if a perforation is suspected.

Perform a digital rectal examination to document the presence and quality of anal sphincter tone after the procedure. This should be delayed until the effects of any general, local, or regional anesthesia have dissipated. Rectal tone that is decreased or diminished from the preprocedural digital rectal examination requires the consultation of a General or Colorectal Surgeon.

AFTERCARE

Patients may be discharged home after the extraction procedure if they are asymptomatic, have normal rectal tone, and have no complications demonstrated on rigid rectosigmoidoscopy. They should be instructed to return to the Emergency Department immediately if they develop abdominal pain, pelvic pain, bright red blood per rectum, or a fever.

COMPLICATIONS

The major complications include rectal bleeding, bowel or rectal perforation, and damage to the anal sphincter.² **Since the patient may very well have presented with these complications, it is important to document them or their absence on the preprocedural**

examination. Rectal bleeding is common after a difficult extraction. It is important to rule out a perforation. This can be performed with the rigid rectosigmoidoscope after the extraction.³² Most perforations occur at the rectosigmoid junction, approximately 15 to 16 cm from the anus. Perforation above the peritoneal reflection will result in peritonitis and free air noted under the diaphragm on upright plain radiographs. Perforation below the peritoneal reflection may take several days to manifest pelvic pain, signs of a pelvic abscess, or sepsis. The patient may still be discharged if there is minor rectal bleeding with no evidence of perforation or significant mucosal damage. However, large amounts of bleeding or significant mucosal damage require observation and consultation with a General or Colorectal Surgeon. A Gastrografin enema without the use of the balloon may be used to identify a perforation if there is significant concern. Patients with perforation of an unprepared rectum require surgical intervention and broad-spectrum intravenous antibiotics.³³ Any evidence of acute sphincter damage requires a surgical evaluation for possible debridement. The majority of these lesions are observed, allowed to heal secondarily, and then repaired surgically.

SUMMARY

The majority of rectal foreign bodies can undergo transanal extraction. Removal of rectal foreign bodies should include an appropriate history and physical; biplane abdominal radiographs;

FIGURE 90-5. A sampling of methods to remove rectal foreign bodies. **A.** Foley catheter technique. **B.** Endotracheal tube technique. **C.** Spoons to remove a fragile object. **D.** Ring forceps technique. **E.** Plaster and a tongue depressor are placed in a jar. After the plaster cures, the tongue depressor can be used as a handle to remove the jar.

relaxation of the anal sphincter; firm attachment to the foreign body and slow, firm traction extraction; and postextraction rectosigmoidoscopy. Inpatient observation is indicated if the rectal mucosa is traumatized. The patient should be taken to the

Operating Room if the foreign body cannot be removed in the Emergency Department, if pain control cannot be adequately achieved, if a perforation is suspected, or if removal may result in secondary injury.

Proctoclysis

Hao Wang, Tyson Jay Higgins,
and Richard Dean Robinson

INTRODUCTION

Proctoclysis is also known as rectal infusion, a Murphy drip, or rectoclysis.¹ It is defined as the slow infusion of fluids and/or medications into the rectum as a therapeutic intervention. John Benjamin Murphy, an American surgeon, introduced the infusion of rectal saline solution to treat patients with peritonitis in 1909.^{2,3} This infusion technique was used in World War I to treat soldiers in hypovolemic shock. Proctoclysis was popular during times when intravenous techniques were less advanced.⁴ With the widespread use of intravenous (Chapters 59 and 61 to 64) or intraosseous infusion (Chapter 70) techniques, proctoclysis has become less favorable and is rarely used in Emergency Medicine.¹ It still plays an important role in the resuscitation and treatment of critically ill patients in remote or rural settings, especially by Emergency Medical Technicians (EMTs).

Proctoclysis can be used when sterile fluids are scarce. Nonsterile fluids (e.g., boiled water or tap water) can be infused into the rectum to provide hydration. Proctoclysis is a relatively easy procedure to perform and does not require health care providers skilled at intravenous cannulation. Multiple medications can be quickly and efficiently absorbed through rectal mucosa.⁵⁻⁹ In recent years, the Macy catheter (**Figure 91-1**) has been successfully used to facilitate proctoclysis with fewer complications and higher satisfaction among patients receiving palliative care, those in the Emergency Department, and those in the Intensive Care Unit.^{5,6,10-14} The Macy catheter has proven that proctoclysis can be used as an alternative and efficient route for medication and fluid infusion in the modern era.

ANATOMY AND PATHOPHYSIOLOGY

An understanding of the anatomy of the anorectal canal is necessary to perform proctoclysis. This anatomy is covered in Chapter 88 on anoscopy. The rectosigmoid junction is about 10 to 15 cm proximal to the anus, at which point the lumen sharply angulates anteriorly and to the left. Rectal catheters used for proctoclysis are normally inserted 7.5 to 10 cm (i.e., 3 to 4 inches) from the anal verge in adult patients.

Fluids and medications are absorbed across epithelial cells or via tight junctions between mucosal cells.¹⁵ The rectum does not absorb sodium, chloride, or water well from isotonic solutions. The colon has sufficient capabilities to absorb these substances. When infused via the rectum, drugs migrate into the sigmoid and descending colon. Depending on specific drug composition and administration volume, spreading can vary with a maximal migration generally being reached within 1 hour. The bioavailability is similar to giving the medication orally.

The middle and inferior rectal veins drain venous blood from the lower part of the rectum directly into the inferior vena cava (**Figure 91-2**). Drugs and fluids are directly absorbed into the systemic circulation without entering the liver. This avoids first-pass hepatic metabolism and achieves a greater bioavailability than seen when infusing via other routes (e.g., peripheral venous). A small portion of the absorbent is also delivered directly into the lymphatic system.

INDICATIONS

Proctoclysis can be used in emergent situations for fluid replacement and/or medical treatment when other routes (e.g., oral, sublingual, intravenous, and interosseous) are suboptimal. It can also be used

FIGURE 91-1. The Macy catheter. **A.** The catheter. **B.** The labeled catheter. (Photographs courtesy of Hospi Corp.)

FIGURE 91-2. The venous drainage of the rectum. Note that a Macy catheter has been inserted. (Used with permission from reference 12.)

TABLE 91-1 Some of the Commonly Administered Rectal Drugs^{5,6,8,9,16-19}

Classification	Examples
Analgesics	Codeine, hydromorphone, methadone, morphine, oxycodone, tramadol
Antibiotics	Amoxicillin, ceftizoxime, erythromycin, metronidazole
Anticonvulsants	Carbamazepine, diazepam, lamotrigine, pentobarbital, phenobarbital, phenytoin, valproic acid
Antiemetics	Chlorpromazine, cisapride, diphenhydramine, hydroxyzine, metoclopramide, ondansetron, prochlorperazine, promethazine
Anxiolytics	Clonazepam, diazepam, lorazepam, midazolam
Laxatives	Bisacodyl, docusate, glycerin, mineral oil, sodium phosphates
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Acetaminophen, aspirin, diclofenac, ibuprofen, indomethacin, ketoprofen, naproxen
Others	Atropine, cefoxitin, dexamethasone, furosemide, haloperidol, hydrocortisone, Kayexalate (sodium polystyrene sulfonate), ketamine, lactulose, lidocaine, nifedipine, prednisolone, propranolol, theophylline

in remote locations, prehospital settings, or mass casualty situations where health care providers must administer fluids and medications during resuscitations despite having little or no equipment, nursing and ancillary staff, and supplies. Proctoclysis in these situations is often an emergent intervention providing patients with life-sustaining fluids and/or medications until more traditional routes (e.g., intravenous or interosseous) are established. In recent years, proctoclysis has extended into emergent resuscitation and palliative care.

Different types of fluids can be infused during proctoclysis including isotonic solutions (e.g., normal saline or lactated Ringer's). Different concentrations of dextrose solutions can be used to treat patients with hypoglycemia. However, infusing large amounts of dextrose solution is not recommended due to the resultant hypotonic solution raising the potential for water toxicity. Nonsterile solutions (e.g., oral rehydration solution, boiled water, or tap water) can be infused with caution in treating hypovolemic shock via proctoclysis. Different types of medications can be administered during proctoclysis including analgesics, anesthetics, antibiotics, anticonvulsants, and antiemetics (Table 91-1).^{5,6,8,9,16-19}

CONTRAINDICATIONS

Proctoclysis should not be performed in patients with severe anal strictures or those with a complete imperforate anus. The Emergency Physician should determine whether the rectal catheter will pass through the anus by performing a visual examination and a digital rectal examination. **Digital rectal examination with a well-lubricated, gloved finger is mandatory prior to proctoclysis. Never insert the catheter if resistance to catheter advancement is encountered.** Proctoclysis is also contraindicated if any recent anorectal surgical procedures have been performed and/or in severe genitourinary trauma (e.g., perineal or perianal regions) due to the risk of bowel perforation or active bleeding being relatively high.

Relative contraindications in patients include severe anal pain requiring general anesthesia, anorectal diseases (e.g., abscesses or fistula), or diarrhea. It is also relatively contraindicated as an elective procedure in patients with weak or no anal sphincter tone on digital rectal examination. Proctoclysis should be performed with caution in patients with severe coagulopathies (e.g., thrombocytopenia) and in patients requiring prophylactic antibiotics (e.g., neutropenia, endocarditis, valvular heart disease, or prosthetics) under nonemergent situations. The risk of bacteremia is high. Proctoclysis is relatively contraindicated for long-term use since some drugs (e.g., ergotamine, acetaminophen, aspirin) can cause rectal

ulceration and stenosis. Precautions should be given to patients with spinal cord injury, especially above the T6 level. Such individuals may experience autonomic dysreflexia triggering extreme hypertension leading to stroke, hemorrhage, seizure, and death. Proctoclysis should also be used with caution in patients with increased intracranial pressure or glaucoma. Large amounts of hypertonic solution are relatively contraindicated to avoid dehydration. This is especially important when treating infants.

EQUIPMENT

- Personal protective equipment
- Water-soluble lubricant or Lidocaine jelly
- Drapes
- Rectal tube
- Nonsterile examination gloves
- Bright overhead light source
- Tincture of benzoin
- 2 inch adhesive tape
- Sheets
- Blankets
- Toilet tissues
- Suction (optional)
- Absorbent pad (optional)
- Bedpan (optional)
- Intravenous stand (optional)

Appropriate personal protective equipment (e.g., gown, clothing, gloves, face mask, and goggles) needs to be worn to reduce exposure to patient body fluids and/or bowel contents.

There are many different types of rectal tubes. A relatively novel device is the Macy catheter (Hospi Corp., Newark, CA) designed specifically for proctoclysis (Figure 91-1). The catheter is available in a 14 French size and made of silicone, making it safe for latex-allergic patients. It utilizes a dual-port system on the proximal end with a balloon inflation port and a fluids/medications administration port. The inflatable 15 mL retention balloon secures the catheter in place. This catheter is designed with a blunt distal end with two side holes for medication and/or fluid delivery. Two placement marker lines are located at 10 and 15 cm from the distal end to guide advancement of the catheter. An internal valve prevents fluid backflow. Once the Macy catheter is positioned and secured, its medication port can be secured to the patient's leg or abdomen for continuous infusions. A large Foley catheter, nasogastric tube, or red rubber catheter can be used for proctoclysis if the Macy catheter is not available.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Gain informed consent if possible. No special bowel preparation is required, especially in an emergent situation. The patient should be given an opportunity to voluntarily evacuate their bowels prior to the procedure if no contraindications exist. It is necessary to remove the patient's clothing from the waist down and provide appropriate barriers to protect the patient, the patient's clothing, and the surrounding area from spills. Maintain dignity and privacy by screening the area, and request a chaperon if providing care to a minor or if there is a gender difference or a cultural difference. Place waterproof pads (e.g., Chux) under the patient's hip and buttocks area. Cover the patient

with a blanket to expose only the rectal area. Use an overhead light to clearly visualize the anus.

Proctoclysis can be performed with the patient in one of many positions. The Fowler (i.e., sitting) position, knee-chest position, and ventral (i.e., prone) positions were used for proctoclysis during the early twentieth century. The most popular position used is Sims position (**Figure 90-3C**). This position allows the patient to lay on their left side with the left hip and left lower extremity straight and the right hip and knee bent. It is also called the left lateral recumbent position. Positioning the patient on the left side facilitates fluid migration toward the colon.

A digital rectal examination with a well-lubricated gloved finger is mandatory prior to proctoclysis. The digital rectal examination has many advantages. It will allow the identification of tenderness, strictures, or a complete obstruction that would preclude proctoclysis. It also prelubricates the anal canal making insertion of the rectal tube easier. Lidocaine jelly can be used as a lubricant and anesthetic if the patient has pain.

Fluids and/or medications should be prepared prior to the procedure. A fluid or medication bag can be attached to the patient (e.g., hip, leg, or torso) or on an intravenous stand. The height of the intravenous stand must be adjusted to avoid high-gravity pressure infusion as outlined below.

TECHNIQUE

OLDER CHILDREN, ADOLESCENTS, AND ADULTS

The technique for proctoclysis is similar to performing anoscopy or rigid rectosigmoidoscopy. Choose an appropriate rectal tube and liberally lubricate the distal 15 cm to 20 cm of the tube. **Avoid over-lubricating the rectal tube since it will increase the likelihood of tube retraction (i.e., falling out of the rectum and anus).** Grasp the rectal tube with the dominant hand. Use the nondominant hand to gently separate the patient's buttocks. Instruct the patient to relax by breathing out slowly through their mouth.

Slowly insert the rectal tube with the tip of the tube directed toward the patient's umbilicus. **Give time for the internal anal sphincter muscle to relax.** Gently insert the tube 10 to 15 cm into the anus. **Stop inserting the tube if resistance is encountered.** If a Macy catheter is used, stop inserting it between the two marker lines. Inject the recommended volume of normal saline through the balloon inflation port if using a rectal tube with an inflation balloon. Slowly pull the rectal tube back until it meets resistance or reaches an appropriate length of insertion. The length of insertion is between 7.5 and 10 cm in adults, between 5.0 and 7.5 cm in children, and between 2.5 and 3.75 cm in infants. Final catheter positioning may require subtle adjustment in proportion to the patient's height.

Secure the rectal tube. Apply tincture of benzoin to the buttocks and allow it to dry. Place a loop of tape around the rectal tube, close to the anus, and anchor each end of tape to each buttock to minimize tube retraction and to reduce fluid leakage. **Do not allow the tape to adhere to the anus as it can tear it when removed.**

The infusion should be gravity fed, allowing the rectum to absorb only what is needed. This avoids the high-pressure flow of fluid into the rectum. Raise the height of the infusion bag slowly to an appropriate level above the anus. This is initially 10 to 30 cm above the anus. Open the regulating clamp to fill the tubing. Lower the infusion bag to allow the solution to slowly enter the rectum. Lower the infusion bag further or clamp the tubing if the patient complains of cramping or if fluid leaks from the rectum. Ideally, the height of the infusion bag should ultimately rest at, or slightly above, the patient's hip level. If no intravenous stand is used, lay the fluid or medication bag on the patient's hip, leg, or torso. Infusion time varies with the

volume of the solution and type of medication administered. Clamp the tubing after all the solution is infused to prevent entrance of air into the rectum.

When proctoclysis is completed deflate the balloon. Keep the rectal tube in place if repeat treatment is planned within short intervals. Remove the rectal tube if no further proctoclysis is required.

YOUNG CHILDREN AND INFANTS

Proctoclysis can be performed in children for the same indications as an adult. A smaller size rectal tube is appropriate for children and infants. The Sims position might be challenging for an uncooperative child. Position the child supine and have an assistant grasp, abduct, and flex the child's thighs so they touch the abdomen without compressing the abdominal wall. Gently and slowly separate the buttocks. Slowly advance the rectal tube into the rectum to the appropriate length. Sedatives may be beneficial in an uncooperative child. The remainder of the procedure is performed as described for adults.

ASSESSMENT

Monitor the patient's vital signs closely. Recheck the infusion bag periodically. Monitor the response to medications as when administering via any other route (e.g., oral, intramuscular, or intravenous). Nursing should record volumes given, time the infusion is initiated, absorption rates, and total infusion time. Contact the receiving hospital, if the patient requires transportation to an advanced care facility, during proctoclysis to avoid delays. Continue the efforts to establish more traditional infusion routes (e.g., intravenous and interosseous).

AFTERCARE

Inform the patient of the completion of the procedure. Document any side effects or complications. Record the types and volumes of fluids and/or medications given to the patient in the medical record. Clean the patient. Cover or dress the patient as appropriate.

COMPLICATIONS

Proctoclysis is generally a safe procedure with minimal or no complications. The most common complication is pain. This is minimized by allowing enough time for the anus to relax while gently inserting the rectal tube. The use of a topical anesthetic gel will usually allow the procedure to proceed with minimal discomfort. Other potential minor complications are flatulence, fluid leakage, and stimulation of bowel movements.

Digital rectal examination is mandatory as it will assist in identifying the obstacles to a safe rectal tube insertion. Advancement of a rectal tube in the setting of anorectal obstruction may result in bowel perforation. Patients sustaining perianal trauma are at risk of local tissue and/or organ damage if rectal tube advancement produces a pseudodiverticulum.

Bleeding is usually minimal or none. Minimal bleeding from mucosal irritation is common and self-limited. Abrasions or lacerations of the very thin anoderm may occur when the rectal tube is inadequately lubricated or is not gently advanced. This is self-limited and normally avoided with adequate equipment preparation and technique. Dislodgement of a clot may result in hemorrhoidal bleeding. This is typically controlled with direct pressure, packing of the anal canal with gauze squares, or a 4-0 chromic gut figure-of-eight suture.

SUMMARY

Proctoclysis is an uncommon procedure in the Emergency Department. It can be used as an alternative route for infusion of fluids and medications. Proctoclysis provides a simple, safe, and effective

means to rehydrate and resuscitate patients without significant risk of severe side effects or complications. Proctoclysis does not require sterile technique, special equipment, or advanced training.

The rectal route of administration is effective because the rectal mucosa is highly vascularized and allows rapid and effective absorption, water and salts are absorbed quickly, and the effectiveness of medication delivery has been established clinically. The technique of proctoclysis is often avoided due to the numerous downsides of traditional forms of rectal drug administration.

Orthopedic and Musculoskeletal Procedures

92

Bursitis and Tendonitis Therapy

Dedra R. Tolson, Brandon M. Fetterolf, and Elaine H. Situ-LaCasse

INTRODUCTION

Bursitis and tendonitis are frequent complaints evaluated in the Emergency Department. **Bursitis represents an acute or chronic inflammation of a bursa. Tendonitis involves inflammation surrounding the bony insertion sites of the tendons.** These complaints are usually treated conservatively with the goal of reducing inflammation. Treatment often includes anti-inflammatory agents, application of cold and heat, elevation, and rest. Joint injections (Chapter 97) and soft tissue injections are helpful for the diagnosis and therapy of a variety of musculoskeletal complaints. The goal of aspirating fluid from a joint is to help make a diagnosis or to relieve pressure within a swollen joint. The therapeutic goal of putting a needle into a joint or soft tissue is to deliver local anesthetics and corticosteroid medications for acute pain relief, suppression of inflammation, and increased mobility.^{1,2} Injection therapy along with generalized treatment is a component of a multifaceted treatment regimen that should be considered by the Emergency Physician.

Definitive care can be initiated by the administration of a steroid injection during the patient's presentation. The clinical response to injectable corticosteroids is quite positive.³⁻⁶ The techniques of aspiration and injection are easily mastered. These techniques are generally safe and effective when appropriate guidelines are followed.¹ **Injection treatment does not replace cessation or modification of the offending activity if identified.**

Injection therapies are frequently performed based on anatomic landmarks. Ultrasound (US) can be used to guide injections. **US-guided injections are safer and allow the Emergency Physician to visualize the needle during the procedure when done in the long axis and ensure delivery of the medication to the appropriate area. The use of US decreases complications and increases patient satisfaction.**⁷ This chapter uses landmarks and US-guided injections to provide relief of the patient's symptoms.

ANATOMY AND PATHOPHYSIOLOGY

Bursae are round, fluid-filled, pad-like sacs or cavities. There are approximately 160 bursae in the body. They are usually located at sites of friction (e.g., over joints or areas where tendons pass over bony prominences). Bursae are lined with a synovial membrane and contain synovial fluid. Their primary purpose is to reduce friction when movement occurs and to provide a mechanical advantage for tendon function. Bursitis often results from trauma, chronic overuse, and inflammatory arthritis (e.g., crystal deposition, infection, and rheumatoid arthritis).

Tendons are fibrous connective tissue bands attaching muscles to bones. A synovial sheath containing synovial fluid surrounds most tendons. Tendons mainly transmit forces from muscle to the

skeleton. Pathologic findings are typified by fibrinoid degeneration, inflammation, and mucoid degeneration.⁸

Bursitis and tendonitis are often grouped together because the history, symptomatology, physical examination findings, and treatment for these two inflammatory processes often coincide. **Corticosteroid injections serve to decrease inflammation, provide pain control, and promote healing. The goal of injection into tendon sheaths and bursae is to attain concentrated steroid levels to maximize the local anti-inflammatory effect while minimizing systemic effects.** Bedside US can assist with differentiating between bursitis and tendonitis, and decrease the risk of iatrogenic adverse effects.

INDICATIONS

Perform injections of corticosteroids for an inflammatory bursitis or synovitis when systemic therapy is contraindicated, as an adjunct to physical therapy, or as an adjunct to systemic therapy. Many inflammatory conditions (e.g., articular and nonarticular processes) are improved with corticosteroid injection therapy.^{1,2,9,10} The articular processes improved with injection therapy include crystalloid arthropathies, gout, neuritis, osteoarthritis, pseudogout, rheumatoid arthritis, and spondyloarthropathies. The nonarticular processes improved with injection therapy include adhesive capsulitis, bursitis, entrapment syndromes, epicondylitis, ganglion cysts, neuritis, periartthritis, plantar fasciitis, tendonitis, tenosynovitis, and trigger points.

CONTRAINDICATIONS

Assess the absolute and relative contraindications when contemplating corticosteroid injection therapy. Absolute contraindications include an adjacent acute fracture, allergy or anaphylaxis to local anesthetics, bacteremia, joints containing a prosthesis, overlying cellulitis, septic arthritis, and unstable joints.¹¹ Relative contraindications include anticoagulant therapy, coagulopathy, joints that are inaccessible, joints requiring radiographic guidance to ensure proper needle placement, joints with loose bodies, labral tears, meniscal tears, multiple sclerosis, or greater than three injections annually into a weight-bearing joint. Consider systemic conditions (e.g., cardiac failure, diabetes, hypertension, and renal failure) that may be affected by the injection of corticosteroids prior to performing injection therapy.

EQUIPMENT

■ GENERAL SUPPLIES

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- Sterile drapes and towels
- Needles, various gauges, 1.5 to 2 inches long
- Syringes (1, 5, and 10 mL)
- Injectable steroidal preparation (**Table 92-1**)
- 1% and 2% lidocaine without epinephrine

TABLE 92-1 Corticosteroid Preparations Available for Injection

Generic name	Trade name	Strength (mg/mL)	Relative potency	Dose range (mg)	Biological half-life (h)
Hydrocortisone acetate	Cortef, Solu-Cortef	25	1	12.5–100	8–12
Triamcinolone acetonide	Kenalog – 10	10	2.5	4.0–40	18–36
	Kenalog – 40	40	10.0		
Triamcinolone hexacetonide	Aristospan	20	8	4.0–25	18–36
Dexamethasone acetate	Decadron, Hexadrol, Dexone	4, 8	20–30	0.8–4.0	36–54
Betamethasone sodium phosphate	Celestone	6	20–30	1.5–6.0	36–54
Methylprednisolone acetate	Medrol, Depo-Medrol, Solu-Medrol	20, 40, 80	5, 10, 20	4.0–30	18–36

- 0.25% and 0.5% bupivacaine without epinephrine
- 1% mepivacaine without epinephrine
- Adhesive bandages

■ ULTRASOUND SUPPLIES

- US machine
- High-frequency linear transducer
- Sterile transducer cover
- Sterile towels

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain a written informed consent to perform the procedure. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Position the patient so that they are comfortable and the injection site is easily accessible. Identify the injection site using the appropriate anatomic landmarks. It may be necessary to outline structures with a skin marker when landmarks are difficult to palpate. Clean any debris and dirt from the skin. Apply povidone iodine or chlorhexidine solution over the injection site and surrounding skin. Allow it to dry. Sterile drapes and gloves are recommended for the novice but are not necessary depending on operator experience.¹² Apply sterile drapes or towels to delineate a sterile field. **A no-touch technique is indicated if a sterile field is not created.**

Prepare the US transducer if using US with the procedure. Have an assistant apply US gel over the footprint of the transducer. Instruct the assistant to place the gel-coated US transducer in the sterile cover while you hold the cover. Have the assistant place sterile ultrasound gel over the transducer or the patient.

TECHNIQUES

Medication dosing in bursae and soft tissue injections is influenced by the bursa size, the presence or absence of synovial fluid, the presence or absence of edema, the severity of synovitis, and the steroid preparation selected.^{13–15} **Table 92-1** summarizes the characteristics of commonly available corticosteroid preparations. The duration of action is chiefly dependent on the solubility of the preparation. A dose of 20 to 30 mg of methylprednisolone acetate or equivalent is appropriate for large spaces (e.g., the olecranon, subacromial, and trochanteric bursae). This can be increased to 30 to 40 mg if a large amount of synovial fluid is present. A dose of 10 to 20 mg is appropriate for intermediate-size bursae (e.g., heel, knee, and wrist). A dose of 5 to 15 mg is appropriate for tendon sheaths.

Triamcinolone hexacetonide and acetonide are the least soluble and most potent preparations available. The local effects of these steroid preparations may take several days to be noticed but will last weeks or months. More soluble preparations such as hydrocortisone

acetate have effects that last a few days. Many prefer triamcinolone due to its prolonged duration of action.

Corticosteroids are often mixed with a local anesthetic solution prior to injection. The local anesthetic solution provides immediate pain relief for the patient. It confirms that the injection was placed at the appropriate anatomic site. Consider using higher concentrations of local anesthetics (e.g., 2% lidocaine instead of 1%) if less volume is needed for the injection.

The sites for joint injections are typically based on anatomic landmarks when superficial bursitis, tendonitis, and large effusions are involved. US may be helpful if available and depending on experience when deep bursae are involved or the target structure is difficult to reach.^{8,16,17} Deep injections requiring US guidance may require a specialist. The procedure can be time consuming and difficult to perform for the Emergency Physician who may not possess the skills and experience with US-guided procedures. These injection procedures can be performed with experience.^{8,16,17} An Emergency Physician can guide the needle to the exact location to inject if they can find the inflamed bursa or tendon using US.

SUBACROMIAL BURSITIS

The subacromial bursa lies between the rotator cuff muscles inferiorly (i.e., supraspinatus, infraspinatus, teres minor, and subscapularis muscles) and the overlying acromion, teres major muscle, and deltoid muscle.¹⁸ It cushions the coracoacromial ligament from the supraspinatus muscle. The subacromial space contains the long head of the biceps, the rotator cuff tendons, and the subacromial bursa. The syndromes of calcific tendonitis, supraspinatus tendonitis, and subacromial bursitis are so similar that the signs of each are difficult to distinguish. Anatomic proximity may cause associated irritative inflammation of adjacent structures so that these conditions often overlap and coexist. Pain from these syndromes is elicited by shoulder abduction.

Patients often present holding the affected arm in a protective fashion against the chest wall. The classic sign of subacromial bursitis is tenderness over the greater trochanter that disappears with arm adduction.¹⁸ The “subacromial painful arc” is painful active abduction of the shoulder with maximal pain occurring between 70° and 100° of abduction. This differs from acromioclavicular joint inflammation which results in a painful arc from 120° to 180° of shoulder abduction.

Three techniques are described to inject the subacromial bursa: the lateral approach, the anterior approach, and the posterior approach. The lateral approach is the most commonly used technique. Some prefer the anterior or subcoracoid approach provided that the Emergency Physician has good familiarity with the anatomic landmarks. This approach is more difficult for the less experienced to perform.

Place the patient seated upright or supine on a gurney. Palpate the indentation under the acromion process of the scapula for the lateral approach. This indentation is located between the acromion process and the greater tuberosity of the humerus. Fill a syringe with

FIGURE 92-1. Lateral approach for subacromial bursitis. **A.** Schematic illustration. **B.** US image. (Courtesy of Dr. George Koulouris, MD, Melbourne Radiology Clinic.)

1 mL of local anesthetic solution and 1 mL of a selected corticosteroid such as dexamethasone. Apply a 22 to 25 gauge needle to the syringe. Insert the needle into the indentation and direct it superomedially. Advance the needle until the tip touches the inferior surface of the acromion (**Figure 92-1A**). Inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage.

US can be used to perform the injection (**Figure 92-1B**).^{18,19} Identify the subacromial bursa with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the bursa. Inject the steroid-anesthetic mixture under US guidance.

Alternative approaches include the anterior and posterior approaches. Position the patient as above for the anterior approach. Identify the coracoid process of the scapula. Insert the needle 1.5 cm lateral to the coracoid process. Direct the needle horizontally and posteriorly. Advance the needle approximately 2.5 cm to gain direct access to the subacromial space. Inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage.

The posterior approach may be used. The distance from the coracoacromial ligamentous arch in this approach is great and may limit efficacy. Place the patient sitting upright with the affected forearm resting in their lap. Palpate the most lateral point of the acromion

FIGURE 92-2. Posterior approach for subacromial bursitis.

process posteriorly. Insert the needle at this landmark. Aim the needle toward the center of the humeral head and at an upward angle of 10° (**Figure 92-2**). Advance the needle 3 to 5 cm until the bursa is entered. Inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage.

SHOULDER IMPINGEMENT SYNDROME

A shoulder impingement syndrome results from rotator cuff, particularly the supraspinatus muscle, compression between the humerus and the coracoacromial arch.^{18,20} This is part of a pathophysiologic continuum with an endpoint of complete rotator cuff rupture in some cases. A history of overhead activities (e.g., painting a ceiling) is common. The clinical hallmark is a painful arch of abduction from 60° to 120°. Pain typically begins at 60° to 70° of abduction and is maximal from 100° to 120°. Tenderness at the tendon insertion site over the greater tuberosity of the humerus may be present.

The impingement injection test may separate the pain of impingement from other causes of shoulder pain. Prevent scapular rotation by holding the patient's scapula against their rib cage. Extend the patient's affected arm in forced forward elevation. Pain with this movement may signify numerous inflammatory shoulder conditions. Repeat this maneuver after injecting 10 mL of local anesthetic solution beneath the anterior acromion process. The absence of pain after local anesthetic injection defines an impingement syndrome.

Place the patient sitting upright or supine on a gurney. Identify the coracoacromial ligament, which is found by palpating the coracoid process and the tip of the acromion process. The coracoacromial ligament connects these two bony points (**Figure 92-3**). This

FIGURE 92-3. Injection for painful arch (impingement) syndrome.

ligament is a thick, dense, and fibrous band. Fill a syringe with 80 mg of triamcinolone and 2 mL of bupivacaine or mepivacaine. Apply a 22 to 25 gauge needle to the syringe.²¹ Insert the needle under the coracoacromial arch and inject the steroid-anesthetic mixture (**Figure 92-3**). **The plunger should depress easily and without resistance. Forceful injection indicates that the tip of the needle is within the rotator cuff tendons.** Advance the needle another 0.5 cm and reattempt the injection, seeking minimal resistance. Withdraw the needle and apply a bandage.

BICIPITAL TENDONITIS

The long head of the biceps tendon passes through the bicipital groove of the humerus (**Figure 92-4**). The inflamed biceps tendon is tender to palpation along the anterior humerus.²² Yergason's test is a clinical indicator of bicipital tendonitis.²² Flex the patient's elbow 90°. Grasp the patient's affected arm as if shaking hands. A positive test is the elicitation of pain in the biceps muscle while providing resisted supination to the patient's hand. Lipman's test is another clinical indicator of bicipital tendonitis.²² Tenderness of the bicipital tendon as it is rolled or plucked within the bicipital groove is considered a positive test. Pain causes restricted motion. Shoulder elevation will aggravate the patient's symptoms.

Place the patient seated with the affected arm externally rotated 20°. The bicipital groove and tendon are now pointing directly anterior. Fill a syringe with 10 to 15 mg of triamcinolone and 2 mL of local anesthetic solution. Apply a 22 to 25 gauge needle to the syringe. Palpate the bicipital tendon and identify the point of maximal tenderness. Insert and direct the needle into the tendon sheath and aimed toward the border of the bicipital groove at the site of maximal tenderness (**Figure 92-4A**). Inject one-third of the dose into the peritendinous space (**Figure 92-4A-1**). **Confirmation of the needle placement within the tendon sheath is made by free flow of the steroid-anesthetic mixture with minimal resistance. Difficulty depressing the plunger indicates that the tip of the needle is within the tendon.** If resistance to injection occurs, withdraw the needle slightly and aim more parallel to the tendon to allow penetration of the sheath and not the tendon substance. Withdraw the needle to just under the skin and redirect it 2.5 cm superiorly. Touch the border of the bicipital groove and inject another one-third of the

dose (**Figure 92-4A-2**). The final one-third of the dose is deposited by again withdrawing the needle to the subcutaneous area and redirecting the tip 2.5 cm inferiorly to the first injection site and touching the border of the bicipital groove (**Figure 92-4A-3**). Withdraw the needle and apply a bandage.

US can be used to perform the injection (**Figure 92-4B**).²² Identify the biceps tendon with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the biceps tendon. Inject the steroid-anesthetic mixture under US guidance.

LATERAL EPICONDYLITIS (TENNIS ELBOW)

Lateral epicondylitis, or tennis elbow, is pain at the origin of the wrist and finger extensor muscles.^{14,23-25} Pain is elicited on palpation of the lateral epicondyle of the humerus. It is also elicited during resisted wrist extension. A history of biomechanical exposure at work, manual labor, and playing racquet sports is common.²⁶

Locate the injection site by palpating the base of the lateral epicondyle with the elbow flexed 90°. Fill a syringe with 1 mL of local anesthetic solution, 1 mL of methylprednisolone, and 0.5 mL of dexamethasone. Apply a 22 to 25 gauge needle to the syringe. Alternatively, mix the local anesthetic solution with 40 mg of triamcinolone. A total volume of 2 mL is required. Insert the needle in the indentation between the lateral epicondyle and the radial head, beginning at the radial head (**Figure 92-5A**). Slowly advance the needle toward the lateral epicondyle. **The radial nerve runs in this area, and care must be taken not to penetrate and inject the nerve.** Paresthesias and pain will be felt if the needle enters the nerve.

Inject 0.5 mL of the steroid-anesthetic mixture into the tenoperiosteal junction at the base of the lateral epicondyle. Withdraw the needle until the tip is at the level of the radial head while simultaneously infiltrating with 0.25 mL of the steroid-anesthetic mixture. Infiltrate 0.5 mL of the steroid-anesthetic mixture when the tip of the needle reaches the level of the radial head. Redirect the needle over the proximal extensor muscle bellies (**Figure 92-5B**). Inject the remaining steroid-anesthetic mixture in a fan-like pattern over the extensor muscle bellies (**Figure 92-5B**). Withdraw the needle and apply a bandage.

FIGURE 92-4. Injection for bicipital tendonitis. **A.** Schematic illustration. **B.** US image. The hyperechoic ovoid structure in the center of the screen is the biceps tendon (arrow) in short axis with fluid surrounding it (i.e., the "halo sign"). (Courtesy of Srikanth Adhikari, MD.)

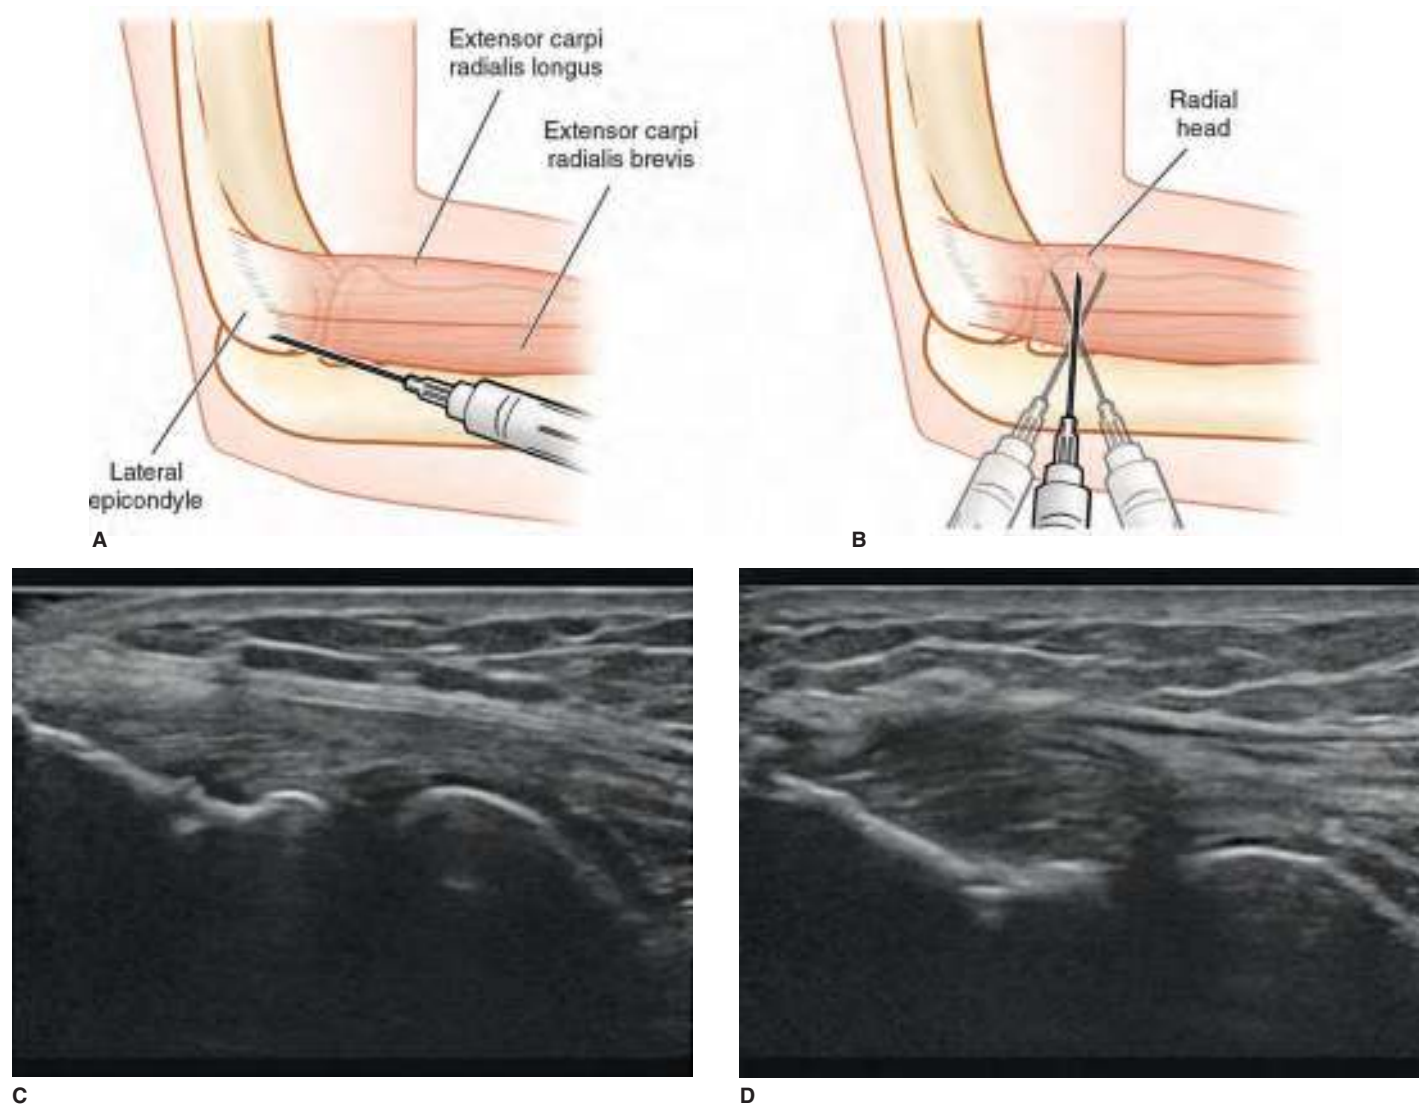

FIGURE 92-5. Injection for lateral epicondylitis. **A.** The needle is inserted at the level of the radial head and advanced to the base of the lateral epicondyle. **B.** The needle is redirected in a fan-like pattern over the muscle bellies. **C.** Normal US image. **D.** Thickened extensor tendons at insertion. (US images courtesy of www.ultrasoundcases.info.)

US can be used to perform the injection (**Figures 92-5C and 92-5D**).^{23,24,27} Identify the origin of the extensor muscle bellies with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the area. Inject the steroid-anesthetic mixture under US guidance.

MEDIAL EPICONDYLITIS (GOLFER'S ELBOW)

Patients affected with medial epicondylitis, or golfer's elbow, are most commonly Little League pitchers, golfers, and bowlers.^{14,28} Pain is felt in the medial aspect of the elbow upon flexion and supination of the wrist.²⁸ Tenderness is elicited on palpation just distal to the medial epicondyle. Exclude an avulsion fracture of the medial epicondyle, a compression fracture of the subchondral bone of the lateral condyle, or a radial head compression fracture in children with nonfused epiphyses. Radiographs are suggested to exclude these causes.

Place the patient supine on a gurney. Place the arm in 90° of external rotation and abducted 90°. Flex the elbow 90°. Prepare a steroid-anesthetic mixture similar to that used for lateral epicondylitis. Fill a syringe with 1 mL of local anesthetic solution, 1 mL of methylprednisolone, and 0.5 mL of dexamethasone. Apply a 22

to 25 gauge needle to the syringe. Alternatively, mix the local anesthetic solution with 40 mg of triamcinolone. Identify by palpation the volar surface of the medial epicondyle. Insert the needle 2 cm proximal to the medial epicondyle and advance it distally to the tenoperiosteal region (**Figure 92-6A**). **The ulnar nerve is better protected than the radial nerve as it runs posterior to the epicondyle. Proximal needle insertion prevents striking the ulnar nerve.** Paresthesias and pain are indicators of nerve penetration. Inject 1.5 mL of the steroid-anesthetic mixture over the medial epicondyle while withdrawing the needle. Withdraw the needle and apply a bandage.

US can be used to perform the injection (**Figures 92-6B and 92-6C**). Identify the flexor muscle bellies with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the area. Inject the steroid-anesthetic mixture under US guidance.

OLECRANON BURSITIS

Olecranon bursitis is usually sterile even though the olecranon bursa is the most frequent site of a septic bursitis.^{29,30} The bursa is located subcutaneously overlying the olecranon process of the

A

FIGURE 92-6. Injection for medial epicondylitis. **A.** Schematic illustration. **B.** Normal US image. **C.** Thickened flexor tendons at insertion. (US images courtesy of www.ultrasoundcases.info.)

B

C

ulna. Olecranon bursitis is not very painful except for the discomfort due to bursal expansion.^{29,30} An enlarged olecranon bursa may limit elbow extension. Studies have demonstrated that corticosteroid injection is superior to oral regimens for resolution of bursal inflammation.²¹ Simple aspiration without corticosteroid injection is often followed by recurrence. **Aspiration with fluid analysis is recommended before corticosteroid injection unless infection can be ruled out clinically.**

Seat the patient upright with their elbow flexed 90°. Fill a syringe with 30 to 40 mg of triamcinolone and 1 mL of local anesthetic solution. Insert an 18 gauge needle on an empty syringe into the most dependent aspect of the bursal sac. Aspirate the bursal fluid to drain it completely. The bursa may be “milked” by palpation and compression of the tissues toward the draining needle. Hold the needle securely. Remove the syringe while the tip of the needle remains within the bursa. Attach the syringe containing the steroid-anesthetic mixture. Inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage. Wrap the elbow region with an elastic compression bandage (e.g., Jones compression dressing) for 7 to 10 days. Instruct the patient to limit elbow movement for 7 to 10 days to prevent reaccumulation of the fluid.³¹

US can be used to perform the injection (**Figures 92-7A and 92-7B**).³⁰ Identify the olecranon bursa with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the bursa. Inject the steroid-anesthetic mixture under US guidance.

DE QUERVAIN'S TENOSYNOVITIS

De Quervain's tenosynovitis is an inflammation of the tendon sheaths of the abductor pollicis longus and extensor pollicis brevis muscles as they cross the wrist (**Figure 92-8A**).^{14,32} The precise cause is unknown. Excessive friction resulting from overuse of the thumb and wrist (e.g., repetitive and excessive gripping) may be a possible etiology. Cases have been seen in bricklayers, golfers, piano players, and those who sew. Pain is elicited by the classic Finkelstein test. The patient is asked to make a fist while flexing the thumb across the palm of the hand. The patient is then asked to sharply ulnar deviate the wrist (**Figure 92-8B**). Palpation along the course of the tendon will also cause pain.

Fill a syringe with 40 mg of triamcinolone and 1 to 2 mL of mepivacaine or bupivacaine. Apply a 25 gauge needle to the syringe. Bending the needle approximately 30° at its base makes it easier to negotiate the area and insert the needle alongside the tendon.³¹ Introduce the needle through the skin overlying the point of maximal tenderness. This is usually just distal to the radial styloid process (**Figure 92-9**). Inject the steroid-anesthetic mixture into the tendon sheath. **Resistance to injection signifies that the tip of the needle is within the tendon.** Withdraw the needle slightly and reinject, feeling for the loss of resistance. Withdraw the needle and apply a bandage. Apply a light thumb splint for approximately 10 days. The splint is especially useful at night or when there is significant activity.

US can be used to perform the injection (**Figure 92-8C**).³² Identify the inflamed tendon with US. Prepare the skin and US

A

B

FIGURE 92-7. Olecranon bursitis. **A.** Sagittal US image. **B.** Transverse US image. The bursa is markedly enlarged and measured. (Courtesy of Srikar Adhikari, MD.)

transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the tendon. Inject the steroid-anesthetic mixture under US guidance.

TROCHANTERIC BURSTITIS

Trochanteric bursitis typically affects women in the fourth to sixth decades of life.²⁹ It also occurs in ballet dancers from overuse, in runners, or from trauma to the hip. Hip pain often prevents the patient from sleeping on the affected side. Pain is severe when ambulating up any stairs. The deep trochanteric bursa lies between the tendon of the gluteus maximus and the greater trochanter of the femur (**Figure 92-10**). Another bursa lies between the gluteus medius and the greater trochanter (**Figure 92-10**). Pain is elicited on palpation of the greater trochanter of the femur. Pain can be reproduced by hip adduction in superficial bursitis or on a resisted active abduction in deep bursitis.²⁹

The principal bursa lies between the gluteus maximus and the posterolateral prominence of the greater trochanter. Pain may radiate from the greater trochanter down the lateral or posterior thigh and mimics sciatica or hip joint disease. Passive range of motion of the hip is nearly painless in the trochanteric bursitis

A

B

C

FIGURE 92-8. De Quervain's tenosynovitis. **A.** Anatomy. **B.** Finkelstein test. **C.** US image. Note the fluid surrounding the affected tendon sheath and the thickened retinaculum. (US image courtesy of www.ultrasoundcases.info.)

in contrast to the previous listed syndromes. Active abduction of the affected hip while the patient is lying on the unaffected side increases symptoms. Pain is also elicited by abduction and external rotation of the hip.

Place the patient prone on a gurney. Fill a syringe with 80 mg of triamcinolone and 3 to 10 mL of local anesthetic solution. Apply a 22 to 23 gauge needle on the syringe. Insert the needle at the point of maximal tenderness and aimed toward the greater trochanter. Advance the needle until the tip strikes the greater trochanter. Withdraw the needle 1 to 2 mm and inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage.

US can be used to perform the injection (**Figures 92-11A and 92-11B**).^{33,34} Identify the trochanteric bursa with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the bursa. Inject the steroid-anesthetic mixture under US guidance.

FIGURE 92-9. Injection for De Quervain's tenosynovitis.

ISCHIAL BURSITIS

The ischial bursa lies between the ischial tuberosity and the overlying gluteus maximus (Figure 92-10). It becomes inflamed from trauma or prolonged sitting on a hard surface. Pain may radiate down the back of the thigh and mimic sciatica. Pain can be elicited by applying pressure over the ischial tuberosity.

Place the patient prone on a gurney. Fill a syringe with 30 to 40 mg of triamcinolone and 5 to 10 mL of local anesthetic solution. Apply a 22 to 23 gauge needle to the syringe. Insert the needle over the most prominent section of the ischium. Hip flexion may facilitate palpation of the ischium in obese patients. **Care must be taken not**

to injure the sciatic nerve. Striking the nerve will cause paresthesias across the buttocks and down the leg. Advance the needle until it contacts the ischial tuberosity. Withdraw the needle 2 to 3 mm and inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage.

US can be used to perform the injection (Figure 92-12). Identify the ischial bursa with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the bursa. Inject the steroid-anesthetic mixture under US guidance.

ILIOTIBIAL BAND SYNDROME

Patients with iliotibial band syndrome present with lateral knee pain.³⁵⁻³⁷ This condition is commonly seen in cyclists, dancers, football players, long-distance runners, and long-distance walkers. These patients have a painful limp that is exacerbated with walking or running. Climbing stairs or walking up an incline will increase their pain. Tenderness is elicited with the patient lying supine and knee flexed 90°. Instruct the patient to extend their knee and press over the lateral femoral condyle. Pain will be localized to the lateral femoral condyle. The patient will have pain at 30° of flexion as the iliotibial band slides over the condyle. A positive Renne test occurs when the patient stands with their weight on the affected leg and flexes their knee. Pain at 30° of flexion is considered a positive test.

Place the patient supine on a gurney. Fill a syringe with 80 mg of triamcinolone and 2 mL of local anesthetic solution. Apply a 22 to 25 gauge needle to the syringe. Typically, at 30° of flexion, the iliotibial band is at the midpoint of the lateral femoral condyle (Figure 92-13A). Support the patient's leg in this position to bring the tendon to its most superficial point. Identify the point of maximal tenderness as the patient flexes their knee. Insert the needle perpendicular to the skin and 1 cm inferior to the point of maximal tenderness. Aim the needle superiorly. Inject the steroid-anesthetic

FIGURE 92-10. Selected bursa of the hip region.

FIGURE 92-11. Trochanteric bursitis. **A.** Normal US image. **B.** US image of fluid in the bursa (arrow). (US images courtesy of www.ultrasoundcases.info.)

mixture in an arc from anterior to posterior. The goal is to deposit corticosteroid in the tendon sheath and the surrounding inflamed tissues. **Resistance to injection indicates that the tip of the needle is within the tendon.** Withdraw the needle slightly and reinject, feeling for the loss of resistance. Withdraw the needle and apply a bandage.

FIGURE 92-12. US image of ischial bursitis. Note the mixed echogenicity in the enlarged bursa (arrow). (US image courtesy of www.ultrasoundcases.info.)

FIGURE 92-13. Injection for iliotibial band syndrome. The knee is flexed 30° to bring the tendon to its most superficial position overlying the midportion of the lateral femoral condyle. **A.** Schematic illustration. **B.** US image. (US image courtesy of www.ultrasoundcases.info.)

US can be used to perform the injection (**Figure 92-13B**).³⁶ Identify the iliotibial band with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the iliotibial band. Inject the steroid-anesthetic mixture under US guidance.

ANSERINE BURSTITIS

Anserine or pes anserine bursitis is an inflammation of the bursa located 5 cm below the medial joint line of the knee at the tibial insertion of the gracilis, sartorius, and semitendinosus muscles (**Figure 92-14**).³⁸ The anserine bursa is superficial to the tibial insertion of the medial collateral ligament. The syndrome occurs predominantly in overweight women with osteoarthritis of the knees. It may be found in equestrians. The anserine bursa will be tender to palpation.

Place the patient supine with the affected leg externally rotated. Identify the anteromedial joint line of the knee. The bursa is located inferior to the joint line at the insertion of the sartorius, gracilis, and semitendinosus tendons (**Figure 92-14**). Palpate the area of maximal tenderness at this site. Fill a syringe with 40 mg of triamcinolone and 2 to 4 mL of local anesthetic solution. Apply a 23 to 25 gauge needle to the syringe. Insert the needle and direct its tip into the bursa at the point of maximal tenderness. Inject the steroid-anesthetic mixture into the bursa. Withdraw the needle and apply a bandage.

US can be used to perform the injection (**Figure 92-15**).³⁸ Identify the anserine bursa with US. Prepare the skin and US transducer.

FIGURE 92-15. Anserine bursitis. US image of fluid in the pes anserine bursa (PAB), the tibia (T), and pes anserine tendon thickening (PAT, star). (Used with permission from Imani F, et al: Sonoanatomic variation of pes anserine bursa. *Korean J Pain* 2013; 26(3):249-254.)

Prepare the syringe with the steroid-anesthetic mixture. Reidentify the bursa. Inject the steroid-anesthetic mixture under US guidance.

PREPATELLAR BURSTITIS

Prepatellar bursitis is caused by direct pressure, such as when a person is kneeling on a firm surface.^{29,30,39} It is also known as nun's, rug cutter's, or housemaid's knee. Tenderness and/or crepitance is elicited by direct palpation overlying the patella. Extreme knee flexion causes pain. There is often a fluctuant, well-circumscribed,

FIGURE 92-14. Bursae of the knee.

FIGURE 92-16. A transverse US image of prepatellar bursitis. The hyperechoic region to the left of the image is the patella, and the anechoic fluid superficial to that is the inflamed bursa. (Courtesy of Srikar Adhikari, MD.)

and warm bursal pouch overlying the patella. The prepatellar space is a common site for septic bursitis. Aspiration with fluid analysis is recommended to rule out an infection before any corticosteroid injection is considered.

Place the patient supine on a gurney with the affected knee slightly flexed. Note that the bursa is very superficial and may be entered by passing the needle just through the skin and subcuticular tissues (**Figure 92-14**). Fill a syringe with 30 to 40 mg triamcinolone and 1 to 2 mL of local anesthetic solution. Apply a 23 to 25 gauge needle to the syringe.³¹ Insert the needle into the bursa at the point of maximal fluctuance. Inject the steroid-anesthetic mixture into the bursa. Withdraw the needle and apply a bandage.

US can be used to perform the injection (**Figure 92-16**).³⁰ Identify the prepatellar bursa with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the bursa. Inject the steroid-anesthetic mixture under US guidance.

INFRAPATELLAR BURSITIS

The infrapatellar bursa has two components (**Figure 92-14**).²⁹ The superficial infrapatellar bursa lies between the patellar ligament and the skin. The deep infrapatellar bursa lies between the patellar ligament and the anterior tibia. Inflammation of the superficial bursa occurs due to friction from the overlying skin. Clinically, there is no pain with passive flexion. Active knee flexion and extension causes pain in the deep infrapatellar bursa. Edema and tenderness may be found on both sides of the patellar tendon.²⁹

Place the patient supine on a gurney with the affected leg and knee extended. Palpate the patellar tendon. Identify the superficial inflamed bursa. Fill a syringe with 20 mg of triamcinolone and 1 mL of local anesthetic solution. Apply a 23 to 25 gauge needle to the syringe. Insert the needle into the superficial bursa and inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage.

Patients with deep infrapatellar bursitis have maximal tenderness and swelling both medially and laterally to the patellar tendon. Fill a syringe with 30 mg of triamcinolone and 1 to 2 mL of local anesthetic solution. Apply a 23 to 25 gauge needle on the syringe. **Insert the needle into the infrapatellar bursa, either medially or laterally to the patellar tendon.** Attempt to aspirate, although fluid accumulation is minimal and usually no return will be found. Inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage.

FIGURE 92-17. US image of infrapatellar bursitis. The patellar tendon is attached to the tibia in the middle of the image. The hyperechoic region superficial to it with mixed echogenicity is the inflamed deep infrapatellar bursa. (Courtesy of Srikar Adhikari, MD.)

US can be used to perform the injection (**Figure 92-17**). Identify the infrapatellar bursa with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the bursa. Inject the steroid-anesthetic mixture under US guidance.

ACHILLES TENDONITIS

The Achilles tendon is the largest tendon in the body. Achilles tendonitis is a common condition that causes tightness and pain in the posterior heel region upon first awaking.⁴⁰ **The tendonitis can occur anywhere from its insertion on the calcaneus to its junction with the muscle.** This discomfort improves with ambulation. The Achilles tendon will be tender to palpation and may be visually swollen. Noninjection and nonsurgical treatments include calf stretching, ice, nonsteroidal anti-inflammatory drugs, orthotics, physical therapy, supportive shoes, and rest. **Corticosteroid injection around the Achilles tendon has been associated with tendon rupture.**⁴⁰⁻⁴² Consider reserving this injection for the Podiatrist, Rheumatologist, or Orthopedic Surgeon.⁴²

US can be used to perform the injection (**Figure 92-18**). Identify the Achilles tendon with US. Prepare the skin and US transducer.

FIGURE 92-18. Achilles tendonitis. Fluid is noted around the Achilles tendon (red dot) consistent with Achilles tendonitis. (Courtesy of Srikar Adhikari, MD.)

FIGURE 92-19. Injection for plantar fasciitis. **A.** Schematic illustration. **B.** The thickened plantar fascia (left, red arrows) is seen next to the normal plantar fascia (right). (US image courtesy of www.ultrasoundpaedia.com.)

Prepare the syringe with the steroid-anesthetic mixture. Reidentify the tendon. Inject the steroid-anesthetic mixture under US guidance.

PLANTAR FASCIITIS

Plantar fasciitis is a common problem presenting to the Emergency Department and the Primary Care Physician.^{43,44} Patients typically complain of medial heel pain, particularly after standing for a long period of time. These patients have minimal to no swelling but feel acute tenderness to palpation over the calcaneal insertion of the plantar fascia. Maximum tenderness is palpated just beneath the spring ligament at the insertion of the plantar fascia on the calcaneus. Radiographs may demonstrate a calcaneal spur. **The presence of a spur does not correlate with plantar fasciitis.** Patients may have plantar fasciitis with or without a calcaneal spur. The optimal therapy for these patients is to elevate the heel with a felt heel pad inserted in the shoe. The patient may begin stretching exercises designed to stretch the plantar fascia. This often relieves the condition without an injection. Injection of the calcaneal insertion of the plantar fascia with a steroid-anesthetic mixture is advocated in significant cases where conservative therapy is unsuccessful.⁴³

Place the patient supine on a gurney with the affected leg externally rotated. Fill a syringe with 20 mg of triamcinolone and 1 mL of local anesthetic solution. Apply a 25 gauge needle on the syringe. Insert the needle into the medial aspect of the foot and aimed just anterior to the base of the calcaneus (**Figure 92-19A**). Advance the needle 1.5 cm and inject the steroid-anesthetic mixture. Withdraw the needle and apply a bandage. The patient should avoid weight bearing for 3 to 4 days and immediately begin oral nonsteroidal anti-inflammatory drugs. Refer to Chapter 223 for more details regarding plantar fasciitis.

US can be used to perform the injection (**Figure 92-19B**).^{45,46} Identify the plantar fascia with US. Prepare the skin and US transducer. Prepare the syringe with the steroid-anesthetic mixture. Reidentify the bursa. Inject the steroid-anesthetic mixture under US guidance.

PEDIATRIC CONSIDERATIONS

Injection techniques for pediatric patients are not different than those for adults. Smaller injected volumes may be required depending on the age and size of the child. Soft tissue corticosteroid

injections should be performed by a Rheumatologist or an Orthopedic Surgeon as these injections can affect bone growth, affect cartilage growth, and can damage growth plates.

ASSESSMENT

The patient must be observed for several minutes after the injection. Reexamine the patient to compare preinjection and postinjection tenderness and mobility. The patient's symptoms should abate within a few minutes from the local anesthetic. Lack of relief indicates deposition of the steroid-anesthetic mixture away from the target structure. A second attempt may be performed if the injection site can be properly identified. Otherwise, refer the patient to their Primary Care Physician, a Rheumatologist, or an Orthopedic Surgeon for reevaluation and reassessment.

AFTERCARE

A treatment algorithm is provided in **Figure 92-20**. Instruct the patient to limit movement and weight bearing of the affected area after a corticosteroid injection. The duration of rest is dependent on the injection site. Larger and weight-bearing joints may require up to 2 to 3 weeks of rest, with range-of-motion exercises encouraged. Immobilization with splints or bandages may be necessary to prevent weight bearing. A rehabilitation program including range-of-motion exercises, stretching, and strengthening may be recommended depending on the chronicity and severity of the presenting condition.

COMPLICATIONS

Local infection is rare after corticosteroid joint injection and occurs in 1 in 17,000 to 50,000 injections.^{1,10,47,48} A local reaction consisting of swelling, tenderness, and warmth may occur a few hours after injection and last up to 2 days. This is known as the "postinjection flare" or "steroid flare."¹² It is self-limited, responds to ice packs, and is treated with nonsteroidal anti-inflammatory drugs. The etiology of the steroid flare is attributed to preservatives in the steroid suspension inducing a local synovitis. Steroid flares occur in approximately 2% of patients injected with corticosteroids.¹

Tendon rupture is a theoretical complication thought to be due to corticosteroids weakening the collagen matrix. Tendon ruptures

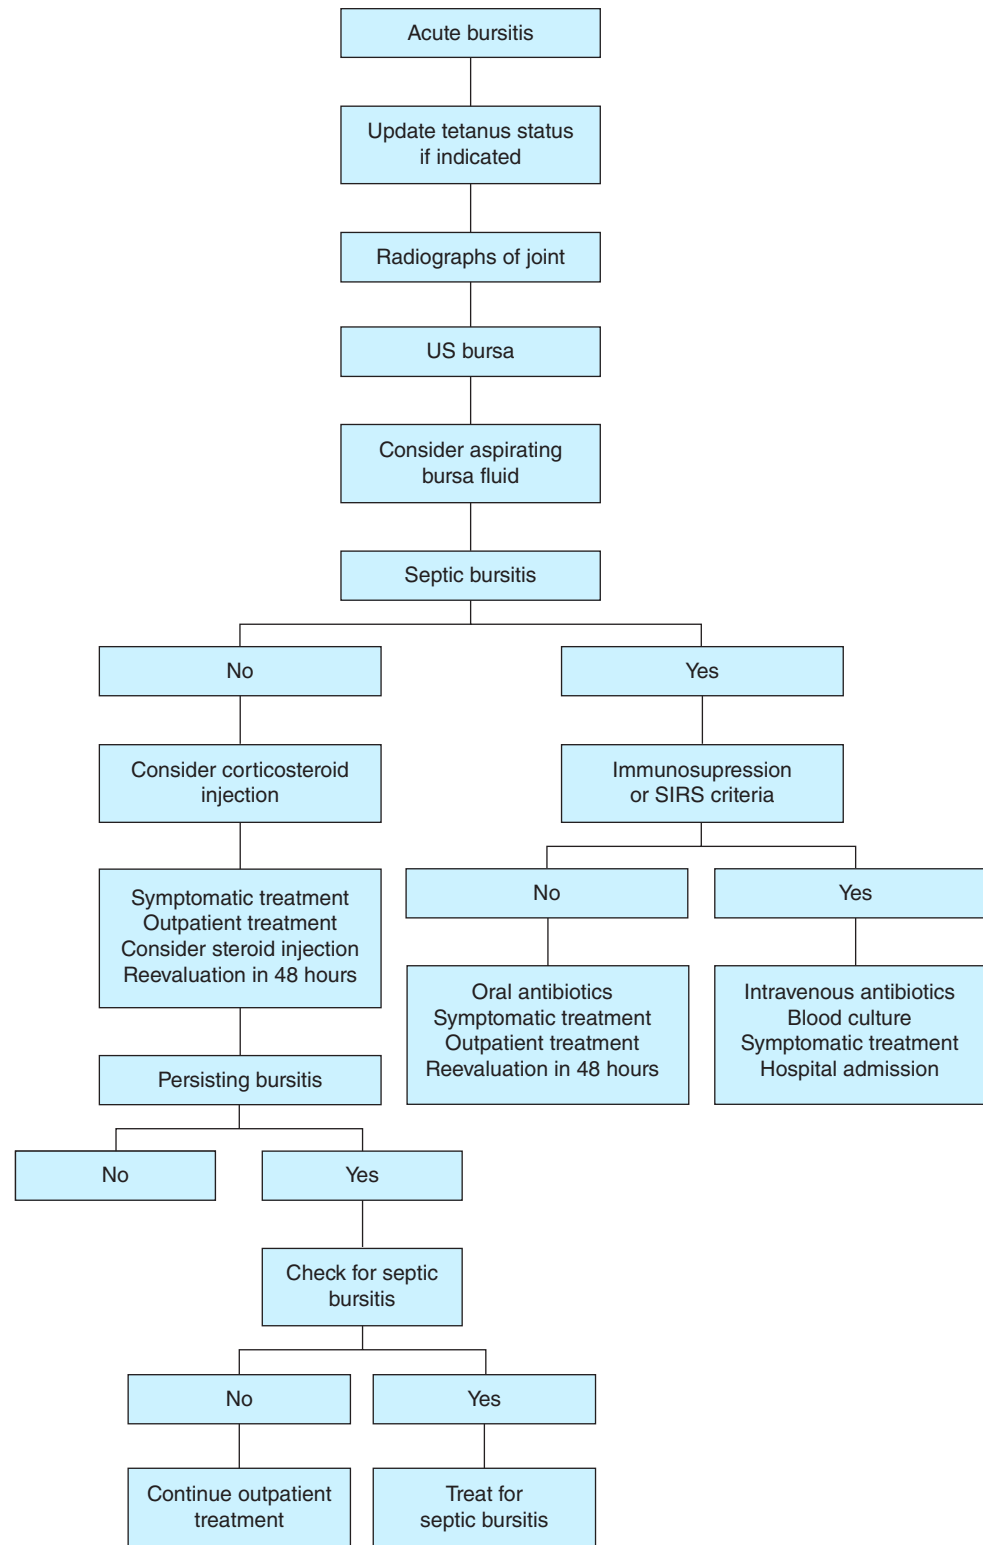

FIGURE 92-20. Treatment algorithm for bursitis. SIRS, systemic inflammatory response syndrome.

after corticosteroid injections have been reported, but direct causality has not been established.^{42,49-52} Rupture is more likely if the injection is made into the tendon matrix rather than the synovial sheath, if the patient does not rest the tendon appropriately after the injection, or with multiple repeat injections.

Subcutaneous fat atrophy and atrophy of the overlying skin may develop if the steroid is injected less than 5 mm beneath the skin surface. A depigmentation in darker-skinned individuals may occur

due to superficial steroid injections. The depigmentation usually resolves spontaneously over a period of 6 months to 1 year.

SUMMARY

Local corticosteroid injections are useful diagnostic and therapeutic adjuncts for the Emergency Physician. Many patients with an inflammatory bursitis or tendonitis will benefit greatly from these simple

and effective injections (**Figure 92-20**). Mastery of the varied techniques is quite easy. They require a familiarity with the indications, the local anatomy, and the injectable corticosteroid preparations. Complications associated with the injection of a steroid-anesthetic mixture are minimal if it is not injected into an infected area.

Compartment Pressure Measurement

Danielle D. Campagne and Scott T. Owens

INTRODUCTION

The ability to diagnose a compartment syndrome is a critical skill for the Emergency Physician (EP). Early identification of a compartment syndrome can enable the appropriate treatment and may facilitate limb salvage. **A compartment syndrome begins when pressure within a myofascial compartment increases to the point**

that it results in diminished blood flow.^{1,2} A compartment syndrome has been classically described in the early literature as a Volkmann ischemic contracture following vascular insufficiency in the forearm.³ A compartment syndrome is described as the 6 Ps (i.e., pain out of proportion, pallor, paralysis, paresthesias, pressure, and pulselessness).

A compartment syndrome can occur in almost any muscle group contained within a confined fascial space. Common locations include the leg, forearm, and gluteal area. There are many causes of a compartment syndrome. These include protracted muscle ischemia (e.g., necrosis from a contusion), swelling (e.g., fracture or volume overload), or a thrombus in a vessel that traverses the compartment. A compartment syndrome in the Emergency Department (ED) is most commonly associated with long bone fractures or blunt trauma.⁴ Most compartment syndromes are caused by trauma.² Approximately 58% of cases are due to fractures of the tibia or forearm.⁵ Other etiologies for a compartment syndrome include complications from a coagulopathy, dialysis, surgery, or states of obtundation (Table 93-1).^{2,6-18}

Identifying a compartment syndrome in a timely fashion can be challenging. The sensitivity and specificity of manual palpation to identify a compartment syndrome are 24% and 55%, respectively.¹⁹ Manual palpation has a positive predictive value of 19% and a negative predictive value of 63%.¹⁹ **Manual palpation cannot be used to rule-in or rule-out a compartment syndrome.**

The hallmark symptom of a compartment syndrome is persistent and progressive pain disproportionate to the underlying cause. The pain typically increases with passive motion. **A common and dangerous mistake is to attribute the etiology of the patient's pain solely to the underlying problem (e.g., fracture or trauma).**^{20,21} Other signs and symptoms associated with a compartment syndrome occur late in the disease course and include

paresthesias of the involved nerve, paralysis of the involved muscle group, pallor of the skin, and diminished pulses.²² **Waiting for the development of all the clinical signs and symptoms to manifest before considering the diagnosis increases the possibility of permanent sequelae (e.g., muscle necrosis and limb loss).** **Measurement of elevated tissue pressure within the muscle compartment is currently the most common and expedient objective means of diagnosing a compartment syndrome.** Compartment pressure measurement provides objective support for the diagnosis of a clinically suspected compartment syndrome and leads to treatments designed to salvage the afflicted limb.

Numerous methods have been evaluated to diagnose a compartment syndrome.²³⁻²⁸ The inflammatory biomarkers and proteins released from damaged muscle are late markers or nonspecific to distinguish between muscle injury from trauma versus a compartment syndrome. Magnetic resonance imaging (MRI) is not reliable or specific to identify the early changes of a compartment syndrome. Pulse phase-locked loop (PPLL) ultrasound and near-infrared spectroscopy (i.e., changes in oxygenated hemoglobin and tissue perfusion) are diagnostic modalities that have been studied and show promise in diagnosing compartment syndromes. These are not yet viable diagnostic tools in the ED due to inadequate sensitivity and specificity.²⁹ Radionuclide imaging is not feasible in the ED due to its lack of specificity, the complexity of the procedure, the time required for testing, and the inability to perform repeated measurements. Pulse oximetry cannot be used to measure intracompartmental oxygenation. It can measure whether distal blood flow is present but is limited by collateral circulation and the loss of pulses being a late finding for a compartment syndrome. Laser Doppler flowmetry measures microvascular perfusion and has potential in the future when more clinical information regarding its use becomes available. Tissue ultrafiltration requires the extraction of tissue fluid and the time-consuming measurement of biomarkers. Evaluating differences in vibratory sensation using a 256 cycle tuning fork shows some promise in the diagnosis of a compartment syndrome. It cannot be used in young children, patients who cannot appropriately communicate, and those with an altered sensorium. Tissue hardness measurement techniques evaluate skin surface pressure and are in the early stages of testing. Direct nerve stimulation is not useful for the early evaluation of a compartment syndrome because nerve damage is a later finding. **None of the above techniques is an adequate substitute for the gold standard of invasive measurement, which is the focus of this chapter.**

TABLE 93-1 Etiologies of a Compartment Syndrome

Anticoagulation therapy or coagulopathy
Blast injuries
Bleeding into compartment
Burns involving muscle (i.e., electrical or thermal)
Chronic exertional compartment syndrome
Eclampsia
Envenomation
Exercise-induced
External compression
Iatrogenic
Iatrogenic closure of fascial injuries
Immobility
Improper casting or tight dressings
Infections
Infiltration of infusion fluids into muscle compartment
Intraosseous infusion leak
Myositis
Nephrotic syndrome (e.g., lower extremity swelling)
Reperfusion after ischemia
Reperfusion injury after prolonged positioning or tourniquet use
Seizures causing increased capillary permeability
Snake bite
Tetany
Trauma
Contusions
Long bone fractures
Blunt trauma (i.e., crush injury)
Vascular injury
Vasculitis
Venous thrombus

ANATOMY AND PATHOPHYSIOLOGY

The anatomy of a compartment syndrome is variable, as it can occur in any enclosed muscle group. Any muscle tissue confined by fascia, skin, or external forces (e.g., casting material) is a potential site for the development of a compartment syndrome. The muscles, nerves, and vasculature within the affected muscle group are all potentially compromised by a prolonged ischemic state followed by swelling. A basic knowledge of the anatomy of commonly affected compartments is necessary to successfully and safely perform compartment pressure measurement.

The initial imbalance of a compartment syndrome occurs between the volume and pressure within the myofascial compartment. The arterial inflow and venous outflow diminish as intracompartmental volume or pressure increases. The blood begins to be shunted via capillaries into the muscle tissue. This compensatory shunting of blood further disturbs the volume-pressure balance and results in impaired tissue oxygenation.^{4,22,30}

The extent of the tissue damage is determined by the duration of ischemia. Numerous experimental studies have documented a

lack of muscle viability after 6 to 8 hours of total ischemia and a lack of nerve viability after 8 hours of total ischemia.^{31,32} **Reversing ischemia before this time is crucial to restoring tissue function.** The definitive factor in the development of a compartment syndrome is the alteration of the pressure gradient between arterial and venous flow. Measurement of the intracompartmental pressures is used to determine the extent of ischemia.

The pressure of a healthy muscle compartment ranges between 0 and 8 mmHg.³³ **There is no absolute value that determines a compartment syndrome.** Consider a fasciotomy at values above 30 to 35 mmHg.^{22,34,35} Several studies have confirmed that a compartment syndrome does not develop definitively at or above 30 to 35 mmHg.^{36,37} A prospective study of patients with isolated lower leg fractures without clinical signs of compartment syndrome showed significant elevations in compartment pressure compared to the contralateral normal leg.³⁸ Other studies use a compartmental pressure that is within 10 to 30 mmHg of the patient's diastolic pressure as one of the indications for a fasciotomy.^{4,31} This "delta pressure" (i.e., diastolic blood pressure minus intracompartmental pressure) has gained popularity in recent years based on literature demonstrating safety and reduction in the number of unnecessary fasciotomies.³⁹ A measurement within 10 to 30 mmHg of the patient's mean arterial pressure is as an indication for a fasciotomy.⁴⁰ **A compartmental pressure that is 30 mmHg or greater requires one to consider the development of a compartment syndrome and the need to perform a fasciotomy.**

Studies have investigated the correlation between the delta pressure or perfusion pressure and a compartment syndrome. A compartment syndrome is suggested if the delta pressure is less than 30 mmHg.^{4,5,31} Adjunctive and noninvasive testing (e.g., T2-weighted MRI and near-infrared spectroscopy) may be helpful in equivocal cases.^{41,42} There is as yet no gold standard for the diagnosis of a compartment syndrome, and it remains a clinical and operative diagnosis despite advances in testing.

A compartment syndrome can occur in any muscle group. This includes the foot, forearm, hand, intercostal spaces, and thigh, to name a few. This chapter reviews the anatomy of the two

most common sites of a compartment syndrome, the leg and the forearm.

Special mention should be made of regional anesthesia with peripheral nerve blocks in the setting of acute musculoskeletal trauma. Regional anesthesia is an increasingly popular approach to the management of pain in traumatic injuries. There exists a theoretical risk of masking the pain symptoms of a compartment syndrome. This is unproven, and regional anesthesia is increasingly common in trauma. **Use extra vigilance in assessing for a compartment syndrome when regional anesthesia has been used for musculoskeletal trauma.**⁴³

LOWER EXTREMITY: LEG

The lower leg consists of four distinct muscle compartments: anterior, lateral, deep posterior, and superficial posterior (**Figure 93-1**). A general understanding of the components of each compartment is important.⁴⁴

The anterior compartment contains the four extensor muscles of the leg. These muscles function together to dorsiflex the foot. The deep peroneal nerve travels through this compartment to innervate the extensors and provide sensory innervation to the web space between the first and second toes. The anterior tibial artery travels through this compartment and provides blood flow to its contents.

The lateral compartment contains the peroneus longus and brevis muscles. Their chief function is to evert the foot, with some abduction and plantarflexion of the foot. The major nerve in the lateral compartment is the superficial peroneal nerve which supplies motor innervation to the compartment muscles and sensory innervation to the lower leg and dorsum of the foot.

A fascial layer divides the posterior muscle group into superficial and deep compartments. The superficial posterior compartment contains the muscles of plantarflexion (i.e., gastrocnemius, plantaris, and soleus). No major nerves or blood vessels travel in the superficial compartment. The deep posterior compartment contains the four deep flexor muscles (i.e., flexor digitorum longus, flexor hallucis longus, popliteus, and tibialis posterior). This group

FIGURE 93-1. Cross section through the middle of the right leg demonstrating the four compartments. The size and proportion of the compartments change as one travels proximally or distally from this middle section. **A.** The contents of the lower leg. **B.** The compartments.

of muscles contributes to inverting and adducting the foot in addition to flexing the foot and toes. The primary sensory innervation is from the tibial nerve which courses through the deep posterior compartment. The tibial nerve supplies most of the muscles of the posterior compartment before dividing into several branches that provide sensory innervation to the sole of the foot. The posterior tibial artery and the peroneal artery are contained within this compartment.

Any of these compartments can suffer from ischemia. **The deep posterior compartment and the anterior compartment have the highest incidence of developing a compartment syndrome.**³⁷ It is difficult to simply observe the patient in the face of a normal compartmental pressure when they clinically present with increasing pain and the features suggestive of a compartment syndrome. **Obtain multiple compartmental syndrome readings and consult a Surgeon when the clinical suspicion is high but the compartmental pressures are normal.**

UPPER EXTREMITY: FOREARM

The forearm consists of three compartments that are interconnected at various levels (Figure 93-2).^{44,45} **This interconnection is significant because release of the pressure in one compartment will reduce some of the pressure in the adjacent compartments. The volar compartment is most at risk for development of a compartment syndrome in traumatic injuries of the forearm.**

The forearm includes the volar, dorsal, and mobile wad compartments (Figure 93-2). The volar compartment contains the hand and forearm flexor muscles, the median and ulnar nerves, and the interosseous arteries (i.e., common, radial, and ulnar). The mobile wad contains the brachioradialis, the extensor carpi radialis brevis, and the extensor carpi radialis longus muscles. No major arteries or nerves are contained within this compartment. The radial artery and a branch of the radial nerve may sometimes lie between the mobile wad and the volar compartment. The dorsal compartment contains the hand and forearm extensor muscles, the posterior interosseous artery, and the posterior interosseous nerve.

INDICATIONS

The earliest and most reliable indication for measuring compartment pressures is the development of increasing pain in a tense and swollen muscle group.⁴ This pain tends to be disproportionate to the underlying cause (e.g., fracture, soft tissue contusion, or thrombus). Pain that increases with passive motion of the affected muscles is an indication for compartmental pressure measurement. Sensory deficits and paresis of the affected muscles are two late findings for the development of compartment syndrome.²² **The presence of palpable pulses and capillary refill do not rule out an evolving acute compartment syndrome.** The absence of pulses may suggest arterial injury or hypovolemia. **Measure and monitor all compartments at risk if the patient is obtunded or unreliable.** This usually refers to the forearm and lower leg compartments in the multiple trauma patient.

Have a very low threshold for measuring pressures within a muscle compartment. Compartmental pressures must be measured if a compartment syndrome is considered as a diagnosis. Do not rely solely on the compartmental pressure measurements to decide the need for a fasciotomy. A compartment syndrome is primarily a clinical diagnosis. Obtain pressure measurements in each compartment at risk and in at least two sites within the compartment. Perform serial measurements or continuous pressure measurement if the initial pressures are normal or only mildly elevated and concern persists. Interpret compartment pressures in the clinical context of the patient. Normal compartment pressures do not rule out the diagnosis.

CONTRAINDICATIONS

There are no absolute contraindications to the measurement of compartment pressures. Obtain compartment pressure measurements while evaluating for coexistent traumatic injuries given the importance of prompt diagnosis. The EP can still assess the compartmental pressures even though the patient may be undergoing other invasive and/or surgical procedures. **Time is of the essence.**

FIGURE 93-2. Cross section through the middle of the right forearm demonstrating the dorsal and volar compartments separated by the line of the radius, the ulna, and the interosseous membrane. **A.** The contents of the forearm. **B.** The compartments. The mobile wad forms a distinct muscle compartment coursing along the radius.

Postponing compartmental pressure measurements or a fasciotomy may lead to irreversible damage to the affected extremity.

EQUIPMENT

■ GENERAL SUPPLIES

- Povidone iodine or chlorhexidine solution
- 4×4 gauze squares
- Sterile drapes or towels
- Skin marking pen

■ NEEDLE (WHITESIDE) MANOMETER TECHNIQUE

- 18 gauge needles, 1.5 inches long
- 20 mL syringe
- Three-port, four-way stopcock
- Intravenous (IV) extension tubing
- Sterile saline
- Mercury manometer

■ STRYKER MONITOR SYSTEM

- Stryker pressure monitor unit
- Sterile, single-use, quick pressure monitor set (i.e., a needle, diaphragm chamber, and syringe)

■ ARTERIAL MANOMETER TECHNIQUE

- 18 gauge needle or Angiocath
- Sterile saline
- Arterial line tubing and manometer identical to that used for arterial lines (Chapter 72)

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Discuss the low risk of bleeding, low risk of infection, and the possibility of obtaining erroneous values. Obtain a written informed consent from the patient and/or their representative if possible. Proceed after documentation of the medical necessity if the patient is unable to consent and no representative is available. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Wash away any blood, dirt, or debris on the patient's skin. Identify the landmarks for needle insertion and mark the skin puncture sites. Apply povidone iodine or chlorhexidine solution to the skin around the puncture sites and allow this to dry. **The measurement of compartment pressures is considered a sterile procedure, and the EP should don a hat, mask, sterile gloves, and a sterile gown.** Create a sterile field with surgical towels or drapes. Reidentify the landmarks for needle insertion and ensure the skin puncture sites are still marked.

The exact locations at which to measure the intracompartmental pressures are not clearly defined. There were no clearly established guidelines for determining the appropriate location for compartmental pressure measurements in patients with fractures prior to the study of Heckman and Whitesides.^{46,47} The results of their study suggest that measurements be performed at the level of the fracture “as well as locations proximal and distal to the

TABLE 93-2 Needle Insertion Sites for the Compartments of the Leg

Compartment	Needle insertion site	Insertion depth (cm)
Anterior	1 cm lateral to the anterior tibial ridge and directed perpendicular to the long axis of the leg	1.0–3.0
Lateral	Just anterior to the posterior border of the fibula and directed toward the fibula	1.0–1.5
Superficial posterior	3 cm medial or lateral to a vertical line drawn through the midcalf	2.0–4.0
Deep posterior	Just posterior to the medial border of the tibia, directed posterolaterally and toward the posterior border of the fibula	2.0–4.0

zone of the fracture.” A 5 cm distance was used from the fracture site to the proximal and distal needle insertion sites. Insert the needle at the point of maximal tightness of the compartment in the absence of a fracture and at least two other sites within the compartment. General anatomic landmarks for needle insertion into the various compartments of the lower leg and forearm are described in **Tables 93-2 and 93-3** and graphically depicted in **Figure 93-3**. **The authors recommend using the highest measured intracompartmental pressure in making the decision for further intervention.**

TECHNIQUES

Several techniques for measuring compartmental pressures have been developed. Some use isolated intracompartmental pressure measurements while others monitor pressure continuously. Obtaining isolated intracompartmental pressure measurements is most important in the ED. The needle manometer method uses a manual manometer and a saline-air meniscus in standard IV tubing connected to a 16 gauge needle.¹² Stryker (Stryker Instruments, Kalamazoo, MI) introduced an electronic system consisting of a reusable digital pressure monitor and a single-use measurement set with a needle, diaphragm chamber, and sterile saline flush.⁴⁸ A technique involving a 16 gauge angiocatheter or needle connected by arterial line tubing to a standard manometer has been described.⁴⁹ All three of these methods will be discussed in this chapter. Data suggest that the Stryker method and the arterial manometer method are significantly more accurate, are more convenient, and require only a small number of components readily available in most EDs when compared to the needle manometer method.^{50,51}

Each of these techniques may be performed with a standard straight needle. All are more accurate if used with a special sideported needle or slit catheter, if available.⁵¹ Similar measurement systems that introduce a wick or slit catheter into the tissue have been shown to be equally effective. Explanations of the wick and catheter techniques have been omitted as they are rarely performed in the ED.

TABLE 93-3 Needle Insertion Sites for the Compartments of the Forearm

Compartment	Needle insertion site	Insertion depth (cm)
Anterior	1.5 cm medial to a vertical line drawn through the middle of the forearm	1.0–2.0
Mobile wad	Perpendicular to the long axis of the radius and into the muscles lateral to the radius	1.0–1.5
Posterior	1–2 cm lateral to the posterior aspect of the ulna	1.0–2.0

FIGURE 93-3. Needle insertion sites to measure intracompartmental pressures. **A.** The leg compartments: anterior (1), lateral (2), superficial posterior (3), and deep posterior (4). **B.** The forearm compartments: anterior (1), mobile wad (2), and posterior (3).

NEEDLE MANOMETER TECHNIQUE

Begin by setting up the system (**Figure 93-4A**). Attach the hub of a 20 mL syringe to the middle port of a three-way stopcock. Attach one end of the IV extension tubing to one of the ports of the stopcock. Attach an 18 gauge needle to the free end of the IV extension tubing. Insert a second 18 gauge needle into a container of sterile normal saline to release the vacuum. Insert the 18 gauge needle

attached to the IV extension tubing into the normal saline until the needle port is well immersed. Open the stopcock ports only to the syringe and the extension tubing. Aspirate the saline to fill one-half of the length of the IV extension tubing. **Make sure that no bubbles enter the system.** Turn the stopcock valve so that the port to the saline is closed.

Attach a second piece of IV extension tubing to the remaining open port of the stopcock (**Figure 93-4B**). Attach the opposite end of this tubing to a manometer or arterial pressure monitor. Remove the 20 mL syringe from the system and aspirate 15 mL of air into the syringe. Reattach the syringe to the stopcock. Remove the extension tubing with the 18 gauge needle from the saline container.

Insert the 18 gauge needle into the affected muscle compartment (**Figure 93-4B**). Turn the stopcock valve so that all three ports are open. Position the IV extension tubing with the normal saline so that the meniscus of the saline-air interface is exactly level with the tip of the needle inserted into the patient's tissue. **The position of the saline-air interface in relation to the tip of the needle is important for an accurate intracompartmental pressure measurement.**

The saline-air interface will form a meniscus when the needle is in the patient. The meniscus will be convex-shaped away from the patient when the tissue pressure is greater than the pressure within the system (**Figure 93-5A**). **Depress the plunger of the syringe gradually and delicately to increase the pressure within the system.** The

FIGURE 93-4. The needle manometer technique. **A.** The initial system setup. **B.** The final system should form a closed system from the manometer through the tissue.

FIGURE 93-5. The air-saline interface. **A.** The air-saline meniscus will form a convex shape away from the patient when the tissue pressure is greater than the pressure of the system. **B.** The meniscus will flatten out when the pressure within the system equals that of the tissue.

shape of the meniscus begins to flatten as the plunger is depressed. **The point where the meniscus is flat and the saline column begins to move equals the pressure within the compartment (Figure 93-5B).** Note and document the pressure on the manometer.

It is important to equilibrate the system between measurements. Pull back on the syringe plunger until the manometer reads 0 mmHg with the needle still positioned in the tissue. Withdraw the needle from the tissue. This will prevent any saline from being deposited in the tissue. The same needle can then be reinserted in another location to obtain additional pressure measurements if sterile technique was used throughout the procedure.

The needle puncture sites will bleed. It is important to complete the procedure by properly dressing the puncture wounds. Apply gauze over the puncture sites and tape it in place. Mild hand-held pressure will tamponade any bleeding.

STRYKER METHOD

The Stryker intracompartmental pressure monitor system is a self-contained device that is convenient, accurate, and relatively easy to use (Figure 93-6). Keep the unit in a secure and easily accessible location. The pressure monitor is battery operated and reusable with a digital display (Figure 93-6A). The quick pressure monitor pack is a disposable, single-patient-use kit that contains an 18 gauge side-ported needle, the diaphragm chamber, and a saline-filled syringe (Figure 93-6B).

Turn the pressure monitor unit on. The digital display should read 0 to 9 mmHg. Use sterile technique when setting up the system. Remove the diaphragm chamber from the quick pressure monitor pack. This chamber ensures sterility between the system and the patient. Place the 18 gauge, 2.5 inch side-ported needle firmly on the smaller tapered stem of the diaphragm chamber (Figure 93-7A). **This needle must remain sterile.** Uncap the 3 mL syringe filled with sterile normal saline and screw it onto the larger stem of the diaphragm chamber (Figure 93-7A). Open the clear plastic lid of the monitor unit. Place the needle-diaphragm chamber-syringe unit on the monitor so that the diaphragm chamber sits in the well (Figure 93-7B). Push down gently on the diaphragm chamber until it is firmly and evenly positioned on the monitor. Close the cover of the unit until a snap is heard at the latch site.

Hold the monitor unit with the needle at a 45° angle from the horizontal. Depress the plunger of the syringe slowly to pass saline through the diaphragm chamber and needle until saline drips from the tip of the needle. This removes any air within the system. Position the needle next to the skin at the angle needed for insertion. Press the “zero” button on the pressure monitor. The display should read “00” after a few seconds. **Insert the needle into the desired compartment at the same angle used during the zeroing process (Figure 93-8).** Slowly inject 0.3 mL of saline into the compartment. This volume of fluid is used to equilibrate with the interstitial fluids. Wait a few seconds as the system is measuring the compartmental pressure. The final compartmental pressure measurement will be displayed on the digital screen. Remove the needle from the patient.

Reset the system to zero before taking additional measurements. This is accomplished by positioning the needle at a new site and desired angle of insertion and pressing the zero button. **This must be repeated between each measurement.** Apply bandages over the skin puncture sites. Mild hand-held pressure will tamponade any bleeding.

An optional indwelling slit catheter set is available for use on the Stryker pressure monitor. This set substitutes a slit catheter, break-away needle, and extension tubing for the side-ported needle. The slit catheter is intended to be left within the patient and allows

FIGURE 93-6. The Stryker intracompartmental pressure monitor system. **A.** The Stryker pressure monitor unit. Note the power switch, zero button, and digital readout. Under the clear plastic cover, the round well will secure the disposable drum and the syringe will clip into the plastic bracket at right. **B.** The quick pressure monitor pack contains (from left to right): an 18 gauge 2.5 inch side-ported needle, the diaphragm chamber, and a 3 mL syringe filled with sterile saline.

multiple sequential intracompartmental pressure measurements. This is not intended for use in the ED.

ARTERIAL MANOMETER TECHNIQUE

The third method of assessing compartment pressures in the ED requires only an 18 gauge needle or angiocatheter, arterial line tubing, and an arterial manometer set up as if for an arterial line (Chapter 72).⁵² Use a straight or side-port needle for a one-time reading. Use an 18 gauge angiocatheter if continuous compartment pressure monitoring is preferable. Attach the desired needle or angiocatheter to the end of the arterial line tubing that leads to the prepared arterial manometer. Flush the entire line with sterile saline. Place the tip of the needle adjacent to the skin insertion site

FIGURE 93-7. Assembly of the Stryker system. **A.** The contents of the quick pressure monitor pack are assembled. **B.** The assembled needle-diaphragm-syringe is placed onto the monitor.

and zero the system. Insert the needle into the compartment and slowly infuse 0.3 mL of sterile saline to equilibrate the system with the interstitial pressure. The manometer will provide continuous real-time measurement of the compartment pressure if the needle or angiocatheter remains in place.

COMPASS PRESSURE MONITOR

The Compass Pressure Monitor (Centurion Medical Products, Williamston, MI) can measure the compartment pressure (**Figure 93-9**). It is a disposable, single-use device that is easy to use. It provides a precise digital qualitative reading instantaneously. Attach a sterile syringe of saline to one end and a sterile needle on the other end. It is used like the Stryker. The device can be used to measure pressure with many procedures (e.g., compartments, central venous lines, intraabdominal, lumbar puncture, and intrapleural).

ASSESSMENT

Measure and document the compartment pressure (**Figure 93-10**). Pressures < 20 mmHg are normal. Pressures of 20 to 30 mmHg are elevated and concerning. They require frequent examination and rechecks of the pressure. Pressures over 30 mmHg or within 30 mmHg of the diastolic blood pressure warrant an emergent evaluation by a General Surgeon or Orthopedic Surgeon for a possible fasciotomy and limb salvage. Obtain an emergent General Surgeon

FIGURE 93-8. The needle is inserted into the desired compartment and the pressure measurement read on the digital display.

or Orthopedic Surgeon consultation if there is any clinical concern for a compartment syndrome regardless of the pressure.

AFTERCARE

Control any bleeding from the skin puncture sites with direct pressure. Mild hand-held pressure will tamponade any bleeding. Apply gauze and tape dressings to all puncture sites. Perform and document a repeat neurovascular exam of the extremity distal to the procedure site.

COMPLICATIONS

There should be no complications for the patient if sterile technique is maintained throughout this procedure. Inserting a needle into a tissue compartment introduces the theoretical risk of infection or damage to the nerves or vessels. No study has shown this to be a significant complication.

A realistic complication of the procedure is obtaining erroneous values.⁵³⁻⁵⁵ The greatest risk to the patient is if an artificially low pressure is obtained and the needed fasciotomy is not performed. False high-pressure readings may be obtained. The consequences of performing an unnecessary fasciotomy are less disastrous. Erroneous values are due to improper technique or device inaccuracy.⁵⁴ Approximately 69% of the time there are technical errors and only 60% with correct technique are within 5 mmHg of the correct pressure.⁵⁴

It is important to understand how the mechanics of the needle manometer system can alter the pressure readings. Injection of

FIGURE 93-9. The Compass. (Photo courtesy of Centurion Medical Products, Williamston, MI.)

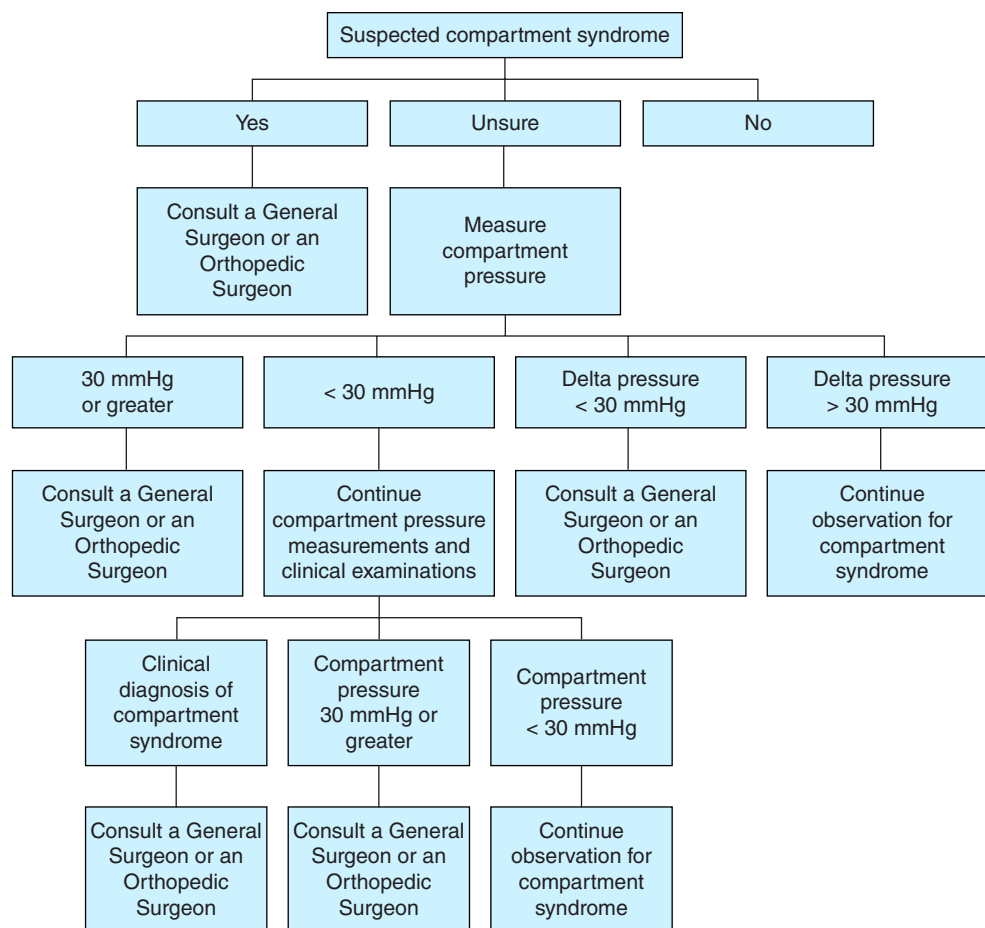

FIGURE 93-10. Algorithm for evaluation of a patient with a suspected compartment syndrome.

normal saline into the tissue will raise the pressure reading. The manometer reading will not accurately reflect the pressure of the compartment if the needle is inserted into a tendon rather than the muscle. A piece of tissue from the compartment can obstruct the needle and lead to erroneous pressure measurements. Failing to match up the saline-air meniscus with the level of the needle in the tissue can produce false pressure measurements.

One must take multiple pressure measurements around the injury site.⁵⁶ To perform a fasciotomy on an isolated pressure reading is to proceed without all the necessary data. It becomes difficult to simply observe the patient when they clinically present with increasing pain and features suggestive of a compartment syndrome when the compartmental pressure measurement is normal. Take multiple readings when clinical suspicion is high and the compartment pressures are normal.

SUMMARY

A compartment syndrome is a well-documented phenomenon. The clinical presentation is variable and changes over time. It is a difficult clinical diagnosis that is critical for the EP to make in a timely fashion. The most common sites are the lower leg and forearm. A compartment syndrome can occur in any muscle compartment of the body. Determining the pressure within a compartment is a fundamental and essential tool to aid in this diagnosis. Many methods exist for the measurement of compartment pressures. The traditional needle manometer system, the Stryker pressure monitor kit, and the arterial manometer are three established techniques that can easily be performed in the ED. These techniques represent the standard of practice in most EDs. Obtain an emergent Orthopedic

Surgeon or General Surgeon consultation if there is any concern for a compartment syndrome (**Figure 93-10**). Continuous observation and repeated measurements are often indicated. Pressures over 30 mmHg or within 30 mmHg of the diastolic blood pressure warrant an emergent evaluation for a possible fasciotomy and limb salvage.

Fasciotomy

Andrew Rotando and Justin Mazzillo

INTRODUCTION

An acute extremity compartment syndrome is a serious and sometimes catastrophic entity that can lead to irreversible local and systemic damage.¹ It is initiated by a variety of injuries and characterized by a cycle of edema and ischemia. **A compartment syndrome is a condition involving increased interstitial pressure in a closed and confined space that results in inadequate perfusion and impaired tissue function.**² The muscles, nerves, and vasculature within the affected muscle group can all be compromised by the edema and prolonged ischemic state with the potential for significant morbidity.

A compartment syndrome may lead to loss of muscle or nerve function, ischemic contractures, rhabdomyolysis, infection, and amputation. This can be followed by systemic complications (e.g., renal failure, sepsis, and possibly death).³ Ischemic contractures of the extremities were first described over 100 years ago by Richard Von Volkmann and are now referred to as "Volkmann's ischemic contractures." Common causes of a compartment syndrome include

anticoagulation, circumferential burns, constrictive dressings (e.g., tight-fitting bandages, casts, or splints), crush injuries, electrical injuries, exercise, external trauma to the extremity, extravasation (e.g., contrast or misplaced injections), joint dislocations, open or closed fractures, reperfusion after a vascular insult, and snakebites (Table 93-1).¹⁻²⁷ Fractures are the most common etiology of a compartment syndrome.^{4,23} Rare causes include unusual circumstances or spontaneous compartment syndrome.^{28,29}

The difficulty in diagnosing a compartment syndrome is that the physical examination is a poor indicator of the degree of microcirculatory compromise.^{5,29,30,31} Common symptoms historically associated with a compartment syndrome have been shown to be unreliable to diagnose and identify a compartment syndrome, and the diagnosis requires a high level of clinical suspicion on the part of the Emergency Physician.^{2,6-8} Refer to Chapter 93 for the complete details of a compartment syndrome.

Treatment of a compartment syndrome with a fasciotomy was first suggested in 1906 by Bardenheuer.⁹ **Maintaining a low threshold for performing a fasciotomy can be the safest course for the patient. The prognosis is more favorable if a fasciotomy is performed soon after the onset of symptoms.**¹⁰ There may be little or no benefit to performing a fasciotomy if it is delayed. A basic knowledge of the anatomy of commonly affected compartments is necessary to safely and successfully perform an extremity fasciotomy.

ANATOMY AND PATHOPHYSIOLOGY

The specific anatomic site of an extremity compartment syndrome is variable, as it can occur in any muscle tissue that is confined in a space by fascia, skin, or any external forces (e.g., casting material). Compartmental perfusion is a dynamic process maintained by arterial blood pressure and limited by the absolute compartment pressure. Increased intracompartmental pressure from edema or hemorrhage within or from external compression of the compartment compromises arterial perfusion, causes venous outflow obstruction, and eventually leads to tissue ischemia.

The muscles, nerves, and vasculature within the affected muscle group are all potentially compromised by a prolonged ischemic state followed by swelling. The initial imbalance of a compartment syndrome occurs between the volume and pressure within the myofascial compartment. The arterial inflow and venous outflow diminish as either intracompartmental volume or pressure increases. The blood begins to be shunted via capillaries into the muscle tissue. This compensatory shunting of blood further disturbs the volume-pressure balance and results in impaired tissue oxygenation.

Skeletal muscles, major nerves, and major blood vessels of the extremities are contained within a noncompliant connective tissue membrane known as the investing or deep fascia. Connective tissue septa extend from the investing fascia to the bones of the extremities. The septa separate major muscle groups and form discrete compartments within each extremity.

The individual fascial compartments have a relatively constant range of pressure within which perfusion is maintained.⁵ The normal compartment pressure is ≤ 12 mmHg. Any of the previously mentioned intrinsic or extrinsic insults may set off a cascade of events leading to edema and/or hemorrhage, causing the pressure within the compartment to rise. A critical pressure is reached within the compartment and perfusion is impaired. This results in altered metabolic processes, cell wall dysfunction, and muscle cell death begins to occur. This leads to extravasation of intracellular contents and edema within the enclosed space, further raising compartment pressures and causing additional cellular injury, and ultimately forming a positive feedback loop.^{2,6}

Skeletal muscle and peripheral nerves can survive ischemic conditions for up to 4 hours before irreversible damage begins to occur. Muscle and nerve injury may still be reversible at 6 hours of ischemia. Ischemia occurring for greater than 8 hours will lead to irreversible damage of muscles and nerves.^{11,32}

DIAGNOSIS

Clinical signs of a compartment syndrome consist of the 6 “P’s” for any region at risk. These include pain on passive stretch of the muscles that run through the compartment, pain out of proportion to exam, paresthesias, pallor, pulselessness, and paralysis. Some may choose to include poikilothermia as the seventh “P.”⁶ **These are generally late clinical findings and may be completely absent early in the disease process except for pain. The most important symptom for diagnosing a compartment syndrome is pain.** Compartment syndrome pain is described as progressive, out of proportion to the examination, occurring with passive movement, and persisting despite immobilization. These symptoms are specific but not sensitive. The absence of pain does not rule out a compartment syndrome.² Palpation to detect a compartment syndrome is highly unreliable. **It is reasonable to measure the compartment pressures when any signs or a clinical suspicion exists for a compartment syndrome.**^{7,8} **The diagnosis of a compartment syndrome relies on the clinical assessment of a combination of factors including mechanism of injury, pain pattern, associated injuries, clinical signs, and compartment pressure measurements.**

The focus of this chapter is to describe the approach to performing fasciotomies of the individual extremity compartments. The pertinent anatomy for each fasciotomy is included. Refer to Chapter 93 for a more detailed discussion of the anatomy, pathophysiology, evaluation, and diagnosis of compartment syndrome.

INDICATIONS

It has been classically taught that a fascial compartment with an absolute pressure of ≥ 30 mmHg will require a fasciotomy. Other factors besides the absolute compartmental pressure contribute to tissue perfusion and should be accounted when deciding to perform a fasciotomy. Hypertension may be protective of perfusion, whereas hypotension may further compromise perfusion.¹ A differential pressure, or “delta P” (ΔP), of ≤ 30 mmHg has been shown to be a better indication for performing a fasciotomy as it accounts for systemic blood pressure.^{5,12-14} The ΔP is calculated as the difference between the diastolic blood pressure and the absolute or measured compartment pressure.

Maintaining a low threshold for performing a fasciotomy can be the safest course in patients who are at high risk of extremity ischemia.^{10,30,31} Any patient with the appropriate history and any of the clinical signs of a compartment syndrome should be considered a candidate for a fasciotomy. Strongly consider performing a fasciotomy if the patient has a fascial compartment with a $\Delta P < 30$ mmHg. An absolute compartment pressure ≥ 30 mmHg, or ≥ 20 mmHg if the patient is hypotensive, combined with any clinical signs of a compartment syndrome is an indication for a fasciotomy. The prognosis is favorable if the fasciotomy is performed within 30 hours of symptom onset.¹⁵ There is usually little or no benefit if the fasciotomy is delayed longer.³² This is particularly true if the fasciotomy is performed greater than 2 days after the onset of symptoms.

CONTRAINDICATIONS

A fasciotomy in the setting of a true compartment syndrome has few absolute contraindications. Any life-threatening conditions must first be addressed. There is a high incidence of severe

infections if a fasciotomy is performed beyond the third or fourth day after symptom onset.¹⁵ A fasciotomy should not be performed if the Emergency Physician is not familiar with the local anatomy or the technique.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Face mask and cap
- Sterile gloves and gown
- Sterile drapes or towels
- Equipment for compartment pressure measurement (Chapter 93)
- 4 × 4 gauze squares
- #10 scalpel blade on a handle
- Tissue forceps
- Metzenbaum scissors
- Curved forceps
- Surgical retractors
- Kerlix dressings
- Splint material

PATIENT PREPARATION

Perform and document a thorough neurological and vascular examination of the affected extremity.¹ Remove any constrictive dressings, casts, and/or splints that may be contributing to the increased compartment pressures. Place the patient supine on the gurney so that the limb at risk is at heart level. It may be more appropriate for the fasciotomy to be performed in the Operating Room by an experienced Surgeon if time is permissible and a Surgeon is available. This is often not possible and the fasciotomy must be performed in the Emergency Department. Consider consulting a Surgeon to assist in the decision to perform a fasciotomy.

Inform the patient and/or their representative of the risks, benefits, complications, and aftercare associated with a fasciotomy. **The procedure must be performed using strict aseptic technique.** The Emergency Physician and any assistants must be wearing sterile gloves, a sterile gown, a face mask, and a cap. Clean the extremity of any blood, dirt, and debris. Apply povidone iodine or chlorhexidine solution to the extremity and allow it to dry. Apply sterile drapes or towels to isolate the extremity and form a sterile field. Collect and place all required supplies on a bedside table covered with a sterile drape. **Use a sterile marking pen to draw the incision lines onto the patient's skin prior to making any incisions.**

A fasciotomy is a painful procedure. Some form of analgesia is required if the patient is conscious. The infiltration of local anesthetic solution provides appropriate analgesia. Ensure that the toxic dose of the selected local anesthetic solution is not exceeded (Chapter 153). Alternatives include a regional nerve block (Chapter 156) or procedural sedation (Chapter 159).

TECHNIQUES

THE ARM

The arm consists of three compartments: anterior, posterior, and deltoid (Table 94-1 and Figure 94-1).¹⁶ The anterior compartment contains the biceps, brachialis, and coracobrachialis muscles. The posterior compartment contains the triceps muscle. The proximal anterolateral arm contains the deltoid compartment.

TABLE 94-1 The Compartments of the Arm and Their Contents

Compartment	Contents
Anterior	Biceps muscle Brachialis muscle Coracobrachialis muscle Brachial artery Median nerve Ulnar nerve Musculocutaneous nerve Lateral cutaneous nerve Antebrachial nerve Radial nerve
Posterior	Triceps muscle Radial nerve Ulnar nerve
Deltoid	Anterior deltoid muscle Lateral deltoid muscle Posterior deltoid muscle Axillary nerve

A fasciotomy of the arm requires two longitudinal incisions to decompress the anterior and posterior compartments (Figure 94-2). Decompress the anterior compartment with a longitudinal incision over the anterior surface of the arm. Make the incision along the midline overlying the biceps muscle extending from the inferior border of the deltoid to the antecubital fossa (Figures 94-1 and 94-2A). Decompress the posterior compartment with a longitudinal incision. Make the incision along the midline of the posterior surface of the arm overlying the triceps muscle from the inferior border of the deltoid to the olecranon (Figures 94-1 and 94-2B). Use a #10 scalpel blade to cut through the skin and subcutaneous tissues down to the level of the investing fascia. Carefully cut the fascia parallel to the skin incision with scissors. **The fascial incision should be the same length as the skin incision. Use caution so as not to cut the muscle itself.**

A fasciotomy of the deltoid compartment muscle may occasionally be indicated. The deltoid muscle has three heads that are separated by septa. It is often necessary to decompress each muscle belly separately.¹⁷ Further complicating the deltoid muscle decompression

FIGURE 94-1. The compartments of the arm. Fasciotomy incisions have been made (arrows) by cutting through the skin, subcutaneous tissues, and deep or investing fascia.

FIGURE 94-2. Fasciotomy incisions of the arm. **A.** Anterior compartment. **B.** Posterior compartment.

is the presence of multiple septa within the respective heads necessitating individual epimysiotomies.¹⁷

Begin the skin incision over the anterior origin of the deltoid muscle (**Figure 94-3**). Extend the incision superiorly and laterally, just lateral to the acromion process. Continue the incision posteriorly along the origins of the posterior deltoid muscle. Use a #10 scalpel blade to cut through the skin and subcutaneous tissues down to the level of the investing fascia. **The cutaneous branch of the axillary nerve becomes superficial inferior and posterior to the acromion and continues anteriorly over the lateral deltoid muscle. It should not be cut when performing a fasciotomy.** Carefully cut open the fascia of the anterior deltoid muscle with scissors. **Use caution so as not to cut the muscle itself.** Measure the compartment pressure in the remaining two muscle heads. Decompressing one head allows the remaining head(s) to sometimes spontaneously decompress. Incise the fascia of the middle head longitudinally. Measure the pressure of the posterior head. Incise the investing fascia of the posterior head if the compartment pressure is still elevated. Explore the full extent of each muscle belly and perform any necessary epimysiotomies to achieve full decompression. To fully decompress the anterior deltoid, it may be necessary to extend the incision distally along the deltopectoral groove. To adequately decompress the posterior head, the incision may need to extend down along the midline posterior arm beginning from the posterior aspect of the acromion.

Alternative techniques have been described in several case reports involving anterior, mid-lateral, or posterior single incisions for isolated deltoid head involvement or two-incision approaches for multiple deltoid head decompression.¹⁸⁻²⁰ The described two-incision

FIGURE 94-3. Fasciotomy incision for the deltoid compartment.

approaches involve a combination of the anterior longitudinal incision for anterior head decompression and either a mid-lateral or posterior longitudinal incision to affect decompression of either, or both, of the lateral and posterior heads. These techniques may be warranted based on patient presentation and physician comfort that full decompression of the affected heads will be achieved.

THE FOREARM

The forearm is one of the most common regions afflicted by a compartment syndrome.^{1,33-35} The forearm consists of three compartments: volar, dorsal, and lateral (i.e., or mobile wad). They are interconnected at various levels (**Figure 94-4**). This interconnection is significant because release of the pressure in one compartment will reduce some of the pressure in the adjacent compartments. **The volar compartment is most at risk for development of a compartment syndrome in traumatic injuries of the forearm.**³⁴ This is followed by the dorsal compartment and the lateral or mobile wad compartment. The lateral or mobile wad compartment is the easiest compartment to decompress because it is located superficially.¹¹

The contents of each forearm compartment are listed in **Table 94-2**. The volar compartment contains all the hand and forearm flexor muscles, the median nerve, the ulnar nerve, the radial artery, the ulnar artery, and common interosseous artery. The dorsal compartment contains the digital and wrist extensor muscles, the posterior interosseous artery, and the posterior interosseous nerve. The mobile wad contains the brachioradialis, the extensor carpi radialis brevis, and the extensor carpi radialis longus muscles. No major arteries or nerves are contained within this compartment. The radial artery and a branch of the radial nerve may sometimes lie between the mobile wad and the volar compartment.

The volar and dorsal compartments can be further subdivided into superficial and deep muscles. Evaluation of the deep muscles becomes important when these muscles are preferentially injured. This includes electrical injury as the bone transmits thermal injury to adjacent muscles, crush injuries, sepsis, and prolonged external pressure on the forearm.

Decompression of the volar compartment can lead to the simultaneous decompression of the other compartments. Thus, a volar fasciotomy is generally performed first.³⁴ There are two approaches employed to perform the volar fasciotomy and one approach for the dorsal fasciotomy (**Figure 94-5**). This text describes the volar-ulnar incision for the anterior fasciotomy (**Figure 94-5B**) and the dorsal approach (**Figure 94-5A**). Some authors feel that the volar-ulnar incision is associated with the least amount of iatrogenic injury.^{1,35,36}

Place the patient supine with their arm supinated on a bedside table to decompress the volar compartment. Begin the incision 1 to 2 cm proximally and 2 to 3 cm laterally to the antecubital fossa. Extend the incision obliquely across the antecubital fossa until it reaches the anterolateral aspect of the distal antecubital fossa. Continue the incision distally on the anterolateral surface of the forearm toward the wrist. Transecting the wrist and extending the incision into the palmar aspect of the hand involves an S-shaped incision. Just proximal to the wrist, extend the incision toward the radial aspect of the forearm being careful to not yet traverse the wrist. **Do not extend the incision as lateral as the radial artery pulse.** Continue the incision back medially and return to the midline of the wrist. Proceed with slight ulnar deviation distally along the midline into the proximal mid-palm. Make a lateral turn along the thenar crease and terminate the incision at the level of the mid-thenar eminence. **Be sure to incise deep enough to include the superficial fascia along the length of the entire forearm without cutting into the muscles or tendons.**

FIGURE 94-4. The compartments of the forearm.

Undertake blunt exploration of the exposed superficial compartment. Identify the median nerve proximally near the antecubital fossa. Release the bicipital aponeurosis at the level of the antecubital fossa where it overlies the median nerve. Retract the flexor carpi ulnaris muscle medially and the flexor digitorum superficialis muscle laterally. Follow the median nerve all the way to the carpal tunnel. Decompress the median nerve at the carpal tunnel. **Be careful**

TABLE 94-2 The Compartments of the Forearm and Their Contents

Compartment	Contents
Lateral (mobile wad)	Brachioradialis muscle Extensor carpi radialis longus muscle Extensor carpi radialis brevis muscle
Dorsal	Extensor carpi ulnaris muscle Extensor pollicis longus muscle Abductor pollicis longus muscle Extensor pollicis brevis muscle Extensor digitorum communis muscle Posterior interosseous artery Interosseous perforators from the anterior interosseous artery
Volar	Posterior interosseous nerve Flexor pollicis longus Flexor carpi ulnaris Flexor carpi radialis longus Flexor carpi radialis brevis Palmaris longus Flexor digitorum superficialis Flexor digitorum profundus Pronator teres Pronator quadratus Radial artery Ulnar artery Anterior interosseous arteries Median nerve Ulnar nerve
Carpal tunnel	Extrinsic flexor tendons Median nerve

not to injure the ulnar artery, ulnar nerve, and the palmar cutaneous branch of the median nerve. Incise the superficial palmar fascia in the midline followed by incising the transverse carpal ligament in the midline.

The superficial forearm contents are completely open at this point, and the deep contents of the volar compartment are exposed and should be explored. Inspect the flexor digitorum profundus, flexor pollicis longus, and pronator quadratus muscles. Use aseptic technique and measure the pressures within the deep muscles to determine whether the fascia covering these muscles needs to be incised. Incise the deep fascial coverings if the muscle pressures are > 20 mmHg.

The major disadvantage to the volar-ulnar incision is that the mobile wad is not easily accessible via this incision. If the mobile wad is at risk, it may be reached through the dorsal incision (**Figure 94-5A**) as described below. It may also be reached through a different volar approach such as the volar curvilinear incision (**Figure 94-5C**). Some authors contend they can successfully decompress all three compartments via this single incision (**Figure 94-5C**).³⁷

Perform a fasciotomy if needed for the dorsal compartment. Place the patient prone with their palm resting on a bedside table. If the patient is supine, completely flex the supinated arm so that the dorsal surface is exposed. Make the longitudinal incision beginning 3 to 4 cm distal to the lateral epicondyle of the humerus and incise to

FIGURE 94-5. Fasciotomy incisions for the forearm. **A.** The dorsal incision. **B.** The anterior volar-ulnar incision. **C.** The volar curvilinear incision.

the distal radius (**Figure 94-5A**).³⁸ Be sure to incise the fascia along the entire length of the incision. **It is important to avoid incising too deep at the wrist and cutting the extensor retinaculum.** If the skin is adequately undermined, the mobile wad will be accessible via this approach.

The carpal tunnel does not contain muscle bellies and is thus not a true compartment. It can achieve acute compartment syndrome physiology.^{17,39} Some authors recommend routinely decompressing the carpal tunnel during a forearm fasciotomy while others maintain that doing so is of limited benefit.^{10,40} This decision is left to the Emergency Physician performing the fasciotomy. **Many important structures run through the carpal tunnel including the median nerve.** Structures within the carpal tunnel become compromised at pressures greater than 40 mmHg. The signs and symptoms will be similar but more severe than a chronic carpal tunnel syndrome.

A carpal tunnel release can be performed as part of the forearm fasciotomy as described above or as an isolated procedure. To perform an isolated carpal tunnel release, begin the skin incision on the proximal portion of the hand between the thenar and hypothenar creases.^{17,40} Extend the incision proximally toward the flexor crease of the wrist. Make a slight ulnar deviation of the incision so that the flexor crease is not crossed at a 90° angle. This will prevent injury to the palmar branch of the median nerve as it courses between the palmaris longus and the flexor carpi radialis tendons. Reflect the skin edges to identify the superficial palmar fascia and the transverse carpal ligament. Make a longitudinal midline incision through the superficial palmar fascia and the transverse carpal ligament.

THE HAND

There are of 11 compartments in the hand. This includes the mid-palm, hypothenar, thenar, adductor pollicis, four dorsal interosseous, and three palmar or volar interosseous compartments (**Figure 94-6** and **Table 94-3**).¹⁷ **Each hand compartment is completely isolated. Decompression or release of one compartment will not help to decompress any of the others.** The pressures required to cause an acute compartment syndrome in a hand compartment may be as low as 15 to 20 mmHg.

Decompress the dorsal interosseous, palmar interosseous, and adductor compartments through dorsal incisions (**Figure 94-7**). Decompress the first and second dorsal interosseous compartments with a 3 to 4 cm long incision over the second metacarpal (**Figure 94-7A1**). Extend the incision into the fascia on both sides of the metacarpal to access the compartments. Using gentle blunt

TABLE 94-3 The Compartments of the Hand and Their Contents

Compartment	Contents
Mid-palm	Extrinsic flexor tendons Lumbrical muscles Superficial palmar vascular arches Deep palmar arches Common digital arteries Common digital nerves Proper digital nerves
Thenar	Abductor pollicis brevis muscle Flexor pollicis brevis muscle Opponens pollicis muscle
Hypothenar	Abductor digiti minimi muscle Flexor digiti minimi muscle Opponens digiti minimi muscle
Dorsal interossei	Dorsal interossei muscles
Volar interossei	Volar interossei muscles
Adductor pollicis	Adductor pollicis muscle

dissection and continue deeper on the radial aspect to access the adductor compartment and on the ulnar aspect to access the first palmar interosseous compartment (**Figure 94-7B**). Decompress the third and fourth dorsal interosseous compartments with a 3 to 4 cm long incision over the fourth metacarpal (**Figure 94-7A2**). Incise the fascia on both sides of the metacarpal to access the compartments. Use gentle blunt dissection on the radial aspect to access the second palmar interosseous compartment and on the ulnar aspect to access the third palmar interosseous compartment.

Access the thenar compartment. Make a 3 to 4 cm long longitudinal skin incision over the thenar muscles on the mediolateral aspect of the hand and just medial to the first metacarpal (**Figures 94-7D** and **94-8**). Continue the incision through the subcutaneous tissues until the thenar muscle fascia is visible. Carefully incise the fascia with scissors. **Be careful to not cut the underlying muscle.**

Access the hypothenar compartment. Make a 3 to 4 cm long longitudinal incision along the ulnar aspect of the fifth metacarpal over the hypothenar muscles (**Figures 94-7E** and **94-8**). Continue the incision through the subcutaneous tissues until the hypothenar muscle fascia is visible. Carefully incise the fascia with scissors. **Be careful to not cut the underlying muscle.**

The mid-palm compartment of the hand is located between the thenar and hypothenar compartments (**Figure 94-6**). Make a 3 to 4 cm long longitudinal incision in the middle of the hand, between the thenar and hypothenar muscles (**Figure 94-7C**). The incision of a fasciotomy of the forearm or carpal tunnel can be extended distally

FIGURE 94-7. Fasciotomy incisions for the hand. **A.** Dorsal and palmar interosseous compartments. **B.** The adductor pollicis compartment. **C.** The mid-palm compartment. **D.** The thenar compartment. **E.** The hypothenar compartment.

to gain access to the fascia of the mid-palm compartment. Continue the incision through the subcutaneous tissues until the fascia is visible. Carefully incise the fascia with scissors. **Be careful to not cut the underlying muscle.**

THE DIGITS

The digits do not contain muscle bellies or true fascial compartments (Table 94-4 and Figure 94-8). The ligaments and restrictive skin create a contained compartment that can exhibit large pressure increases.¹⁷ Cleland's and Grayson's ligaments are constrictive ligaments that encircle the finger and overlie the neurovascular bundles (Figure 94-9). **Measurement of pressures in these "pseudo-compartments" is very difficult. The indications for decompression are based more on clinical findings and suspicion. The fingers and toes have very similar anatomy and are managed in the same manner.**

A fasciotomy of the digit is performed using a single midaxial longitudinal incision along the length of the digit. Make the incision along the ulnar aspect of the index, long, and ring fingers and along the radial aspect of the thumb and small fingers (Figure 94-8). **Be careful to avoid injuring the underlying neurovascular bundle.** Identify the neurovascular bundle and release any constrictive fascial bands from Cleland's or Grayson's ligaments (Figure 94-9). Continue dissecting along the palmar aspect of the flexor tendon sheath and release any vertical bands of connective tissue. A second longitudinal incision can be placed on the opposite side of the digit to decompress the underlying neurovascular bundle if severe swelling is present with dysfunction of both the ulnar and radial neurovascular bundles.

THE THIGH

A compartment syndrome of the thigh is most frequently due to blunt trauma with associated femur fracture, but it is uncommon relative to the overall number of femur fractures.^{3,41} The pressure at

FIGURE 94-9. Cross-section through a digit.

which a compartment syndrome of the thigh develops is not known. A case report of three patients who developed a thigh compartment syndrome in association with a femur fracture noted two of the patients had significant arterial bleeding into the thigh and the third had prolonged extrinsic compression of the leg. The Emergency Physician will need to rely on clinical signs and symptoms, measured pressures, and the mechanism of injury to make the diagnosis of a thigh compartment syndrome.

The thigh contains three compartments. These are the anterior, medial, and posterior compartments (Figure 94-10). They are separated from each other by intermuscular septa. The lateral intermuscular septum is the thickest of the three and separates the anterior and posterior compartments. The contents of the compartments are listed in Table 94-5.

Place the patient supine with their foot pointing upward. Expose the thigh from the iliac crest to the lateral epicondyle.¹⁵ Begin the incision just distal to the intertrochanteric line and extend it to the lateral epicondyle (Figure 94-11A). Expose the iliotibial band, a thickening of the investing fascia, by subcutaneous dissection. Release the anterior compartment of the thigh by making an incision in the iliotibial band that parallels the skin incision. Retract the vastus lateralis muscle medially, carefully separating it from the lateral intermuscular septum, and cauterizing or suturing any bleeding perforating vessels (Figure 94-11B).⁴² Make a 1.5 cm incision in the lateral intermuscular septum using Metzenbaum scissors. Extend the incision proximally and distally to decompress the posterior compartment. Determine the pressure in the medial or adductor

THE LEG

The leg is the most common location for a compartment syndrome, and a tibial fracture is the most common injury leading to a leg compartment syndrome.^{1,9,43} The lower leg consists of four distinct muscle compartments: anterior, lateral, deep posterior, and superficial posterior (**Figure 94-12**).^{15,44} A detailed list of the contents of each compartment is noted in **Table 94-6**.

The anterior compartment contains the four extensor muscles of the leg. These muscles function together to dorsiflex the foot. The deep peroneal nerve travels through this compartment to innervate the extensors and provide sensory innervation to the web space between the first and second toes. The anterior tibial artery travels through this compartment and provides blood flow to its contents.

The lateral compartment contains the peroneus longus and brevis muscles. Their chief function is to evert the foot, with some consequent abduction and plantarflexion of the foot. The major nerve in the lateral compartment is the superficial peroneal nerve to supply motor innervation to the compartment muscles and sensory innervation to the lower leg and dorsum of the foot.

The transverse intermuscular septum divides the posterior muscle group into superficial and deep compartments. The superficial posterior compartment contains the muscles of plantarflexion (i.e., gastrocnemius, soleus, and plantaris muscles). No major nerves or blood vessels travel in the superficial compartment. The deep posterior compartment contains the four deep flexor muscles (i.e., flexor digitorum longus, flexor hallucis longus, tibialis posterior, and popliteus muscles). This group of muscles contributes to inverting and adducting the foot in addition to flexing the toes and foot. The primary sensory innervation is from the tibial nerve which courses through the deep posterior compartment. The tibial nerve supplies most of the muscles of the posterior compartment before dividing into several branches that provide sensory innervation to the sole of the foot. The posterior tibial artery and the peroneal artery are contained within this compartment.

The deep posterior compartment and the anterior compartment have the highest incidence of developing a compartment syndrome.⁴⁵ Recall that a compartment syndrome is progressive, developing over time, and patients may initially present with normal compartment pressures. **Multiple compartmental readings must be taken when the suspicion is high and the compartmental pressures are initially normal.**

A single-incision fasciotomy can be performed if the physical examination of the leg reveals a clinical concern for a compartment syndrome of only one compartment. Decompression of all compartments will be required in cases of prolonged limb compression or severe trauma.^{44,46} Several different techniques are used to decompress all four compartments of the lower leg and involve either a single incision or a double incision. This text describes the double-incision approach. It remains the most frequently employed technique, although there may be advantages to the single-incision approach that could ultimately lead to its widespread use.^{47,48} Researchers have developed an algorithmic approach to acute compartment syndrome of the leg involving the initial decompression of the anterior and lateral compartments with subsequent repeated pressure measurements of the posterior compartments to determine if further decompression remains warranted.⁴⁷ This approach could potentially avoid unnecessary decompression of the posterior compartment if indirect pressure from the anterior and lateral compartments is relieved by the lateral incision, although this necessitates sufficient hospital resources to ensure close monitoring.⁴⁹

Begin the double-incision approach. First perform an anterolateral incision to decompress the anterior and lateral compartments. Make a 20 to 25 cm long longitudinal incision between the fibular

FIGURE 94-12. The compartments of the leg.

shaft and tibial crest (**Figure 94-13A**).¹ **The aim is for the incision to be located over the anterior intermuscular septum, the landmark that guides access to both the anterior and lateral compartments (Figure 94-13C).** Ultrasound could potentially be used to identify the anterior intermuscular septum and allow for a more precise skin incision. How this would perform in the clinical setting has yet to be determined.⁵⁰ Undermine the skin edges to expose more of the fascial covering. Make a small transverse incision through the fascia at the midpoint of the incision to expose the intermuscular septum. **Be cautious not to cut the superficial peroneal nerve that lies just lateral to the septum.** Instruct an assistant to retract the skin edges. Open the anterior compartment using Metzenbaum scissors to cut the investing fascia. Extend the fascial incision longitudinally, both distally and proximally, the length of the skin incision. Decompress the lateral compartment by incising its investing fascia longitudinally in a similar manner.

Perform a second incision along the posteromedial leg to access the posterior compartments (**Figure 94-13B**). The two posterior compartments can be decompressed with one skin incision (**Figure 94-13C**). Make a 20 to 25 cm long longitudinal incision 2 to 3 cm posterior to the posterior tibial margin (**Figure 94-13B**). Undermine the skin and subcutaneous tissues on both sides of the incision. Instruct an assistant to retract the skin and subcutaneous tissue on both sides of the incision. Incise the crural fascia transversely to expose the medial edge of the posterior intermuscular septum. It is located anterior to the soleus muscle, leads inwardly to the transverse intermuscular septum, and divides the deep and superficial posterior compartments. Decompress the superficial posterior compartment. Make a longitudinal incision posterior to the posterior intramuscular septum overlying the soleus muscle. Extend the incision the length of the skin incision. Decompress the deep posterior compartment. Retract the soleus muscle laterally and make a longitudinal fascial incision just posterior to the tibia and anterior to the soleus muscle. This results in incising the transverse intermuscular septum overlying the flexor digitorum longus to access the deep compartment. Extend this incision both proximally and distally.

THE FOOT

The number of compartments within the foot is a matter of controversy (**Figure 94-14**).⁵¹ It was initially believed that there were four compartments. Further research has shown that up to nine compartments exist. Subsequent studies have shown that the barriers between many of these compartments break down at pressures greater than 10 mmHg, far less than that required to cause a compartment syndrome. For the sake of this chapter we will divide the nine compartments into four groups: the interosseous compartment, the medial compartment, the central compartment, and the lateral compartment.¹⁵ A list of the contents of each compartment is noted in **Table 94-7** and **Figure 94-14**.

There are two main approaches used to access the compartments of the foot and both can potentially reach all the compartments.⁵²⁻⁵⁴ The most popular approach is the medial approach which most readily accesses the medial and central compartments (**Figure 94-15A**).

FIGURE 94-13. Fasciotomy incisions for the leg. **A.** The anterolateral incision. **B.** The posteromedial incision. **C.** Cross-section through the leg demonstrating the fasciotomy incisions.

Make the skin incision starting just below the medial malleolus and over the superior aspect of the adductor hallucis muscle. Continue the incision distally along the inferior border of the first metatarsal and superior to the abductor muscle. Retract the skin edges. Identify the neurovascular bundle and retract it out of the way. Incise the fascia of the medial compartment. Continue incising laterally through the medial intermuscular septum of the medial compartment. The remaining compartments can be accessed by blunt dissection with a clamp or by performing additional incisions via the dorsal approach.

The dorsal approach involves two incisions and is best used to access the interosseous compartments and the lateral compartment (**Figure 94-15B**). This approach is superior to the medial approach in the setting of metatarsal or Lisfranc fractures. Make the first incision along the medial aspect of the second metatarsal. Make the second incision along the lateral aspect of the fourth metatarsal. Incise the superficial fascia of each intermetatarsal space and elevate the

muscles off the bone for more effective decompression. Use a clamp to bluntly dissect, access, and decompress the remainder of the compartments (**Figures 94-14 and 94-15B**). The lateral compartment can be accessed and decompressed through the second incision. The central compartment can be accessed and decompressed through either incision. The medial compartment can be accessed and decompressed through the first incision.

ASSESSMENT

Aseptically measure all compartment pressures after each fasciotomy. **Many compartments communicate and a fasciotomy of one compartment may relieve the pressure in others and obviate the need for additional fasciotomies. After the fasciotomy is complete, compartment pressures should be measured again to ensure successful decompression.** Check multiple readings throughout the same compartment.¹ **Ensure that the fascia is completely incised and consider increasing the length of the fasciotomy if the compartment pressures are still elevated.**

AFTERCARE

The compartments and wounds are left open once decompressed. Apply sterile saline-soaked gauze into the incisions followed by a nonrestrictive and bulky dressing wrapped around the limb. The dressing should be loose and allow the wound to easily drain.³⁵ Splint the limb to prevent contractures. The limb must be splinted so that the fractured bones are in appropriate alignment in cases where the decompressed limb has a fracture.³⁶ Consult the appropriate Surgeon (e.g., Hand, Orthopedic, Plastic, or Trauma) to manage the patient. The decision to administer prophylactic antibiotics should be made in consultation with the Surgeon. Admit the patient for further care.

COMPLICATIONS

The goal of surgical decompression is to open the tight fascial layers.³⁶ **Minimizing the length of the skin incisions or limiting the number of compartments decompressed will lead to substandard results.** Continued edema and postischemic hyperemia in the first few hours after a decompressive fasciotomy can lead to increased compartment pressures in adjacent compartments that were not decompressed.

There is a significant risk of an iatrogenic injury to arteries, nerves, tendons, and veins during the fasciotomy.¹ A thorough understanding of the local anatomy and the procedure will help to minimize these injuries. Adequate visualization using proper overhead lighting and proper retraction will further minimize injury.

The diagnosis of a compartment syndrome may be delayed because of a missed diagnosis or because the patient does not present immediately to the Emergency Department. The Emergency Physician may be faced with a situation in which the muscles of the limb are in varying stages of ischemia, irreversible injury, and contracture. Performing a fasciotomy may predispose the limb to secondary infection with subsequent gram-negative sepsis.³⁵ **The Emergency Physician must weigh the risks and benefits before proceeding. The decision to perform a fasciotomy should be made in consultation with a Surgeon.**

Infection after a fasciotomy is a definite possibility. The use of aseptic technique is mandatory but does not prevent subsequent infections. The presence of crush injuries, myonecrosis, poor perfusion, preexisting peripheral vascular disease, and a compromised immune status can predispose the site to an infection. The decision to use broad-spectrum prophylactic antibiotics should be made in consultation with a Surgeon.

Hemorrhage is often minimal when performing a fasciotomy. Most hemorrhage can be controlled with direct pressure. Small subcutaneous blood vessels transected during the procedure can be controlled with electrocautery or figure-of-eight sutures.

SUMMARY

Emergency Physicians must understand the signs and symptoms of a compartment syndrome. Always maintain a high level of suspicion in patients presenting with limb injuries. The technique itself is quite simple when the incision is made in the proper location. Performing a fasciotomy in a timely fashion can prevent serious and irreversible consequences.

Field Amputation of the Extremity

Joshua T. Bucher and Michael S. Westrol

INTRODUCTION

An amputation is an old procedure. Early amputations were crude: amputations were performed without anesthesia, hemostasis was achieved by dipping the amputated extremity in hot oil, and the mortality was high. The first reference to an amputation was found in the ancient Babylonian code of Hammurabi in 1700 BC. Hippocrates described the amputation for vascular gangrene in 385 BC. William Cloves performed the first successful above-the-knee amputation in 1588. The tourniquet was described in the 16th century by Botallus and Holdani. The development of anesthesia in the 16th century made the procedure easier for all involved. Jean Domnique performed 200 limb amputations and 11 shoulder disarticulations. Norman Kick used the guillotine amputation during World War II. This procedure has undergone many advancements since the first

amputations. It is a common procedure, with approximately 65,000 amputations occurring annually usually due to peripheral vascular disease of the lower extremities. An amputation is often performed in a hospital but the acceptance by the patient is still low.

Relatively common situations in which rescuers may find victims entrapped include machinery limb entanglement (e.g., agricultural, construction, or industrial), motor vehicle collisions, confined space rescues, and structural collapses. Rescuers have been able to achieve success in situations that were previously futile as extrication technology has progressed. The methods of safe extrication may be exhausted or the patient's clinical course may not be stable enough to endure prolonged extrication attempts. The actions of extrication can sometimes put rescuers or other victims at risk. This is particularly true in structural collapse situations. A prehospital field amputation of entrapped or entangled limbs may be the only way to save the patient.

Prehospital field amputation is performed infrequently. Very little is published on the overall incidence of the procedure except in case reports.¹⁻¹⁰ It is a lifesaving procedure with several indications to be performed in the prehospital environment. Training in limb amputations is not standardized and is infrequently available in Emergency Medical Services (EMS) agencies for their providers. An interview occurred with Medical Directors at the National Association of EMS Physicians (NAEMSP) meeting in 1992.⁵ The number of prehospital extremity amputations in the prior 5 years was reported to be 26 by the 143 Medical Directors. Almost all (96%) reported there was no formal training in the procedure or its indications.⁵ This highlights the issue of lack of standardization.

Formal training, protocols, and preformed teams are rare.⁵ It is conceivable that a local Emergency Physician or Surgeon may be called upon to assist in a prehospital amputation with no prior formal training or equipment preparation.

The amputation may be achieved with the cutting of a long bone or with a disarticulation at a joint. The joint capsule, tendons, and ligaments are transected in a disarticulation as opposed to cutting the bone in an amputation. Severely mutilated limb injuries may only have minimal connective tissue remaining (e.g., nearly complete traumatic amputations).

ANATOMY AND PATHOPHYSIOLOGY

The anatomy involved in such a procedure is dependent on the limb(s) involved. The entanglement may be as simple as a single digit or as complicated as multiple limbs with proximal involvement. Torso entrapment or crush injury may not be amenable to amputation as a method for rescue. Such situations will not be discussed. Any prehospital amputation procedure of an entrapped extremity includes exposure to skin, tendons and ligaments, muscles, blood vessels, nerves, and bone. The injury may distort the anatomy to the point of being unrecognizable (e.g., a mangled or rotated extremity). The basic anatomy of the extremities is sufficient knowledge to perform a field amputation.

The entrapped patient may be subject to numerous assaults on their body's pathophysiology. Trauma to the limbs may be blunt or penetrating. The patient may have sustained multisystem trauma (e.g., structural collapse or motor vehicle collisions). **Attention must be paid to the patient's overall hemodynamics.** External and internal blood loss from the traumatic injuries can lead to shock and coagulopathy. Fluid resuscitation of the entrapped patient can allow additional field time and further attempts at extrication prior to resorting to an amputation. A large area of limb entrapment may lead to a crush syndrome. The pressure applied to muscle groups and blood vessels by external forces may result in areas of ischemia if the entrapment is prolonged. Subsequent rhabdomyolysis results

in the release of large amounts of myoglobin, potassium, and other cellular contents. This can result in metabolic acidosis and renal failure.¹¹ The management of crush syndrome includes large-volume hydration that must be balanced with permissive hypotension to avoid the dilution of clotting factors.

INDICATIONS

Two sets of indications have been developed for prehospital amputations.^{12,13} They are not mutually exclusive and have some overlap. One set of criteria was developed from experiences from prior case reports and incidents.¹² These criteria tend to be more conservative. They include the dismemberment of a deceased patient to access live patients. Emergency Physicians should be aware that dismemberment of a deceased individual may be taboo in some cultures.⁶ The situation should be discussed, if possible, with the family of the patient prior to proceeding to dismember the deceased.⁶ The other indications established a prehospital extremity amputation protocol for EMS Physicians through the Medical College of Wisconsin which included four situations that may warrant prehospital amputation.¹³ The indications for prehospital amputation are summarized in **Table 95-1**.

CONTRAINDICATIONS

The only absolute contraindication to the procedure is when the Emergency Physician performing the procedure is placed at risk and it is deemed too dangerous. The safety of the rescuers is paramount.¹² One may consider a relative contraindication to be the informed refusal of the procedure by a conscious patient who understands the risk of clinical deterioration during continued extrication attempts. The ethical considerations of such a refusal are beyond the scope of this text. The local hospital ethics board should be emergently consulted in such a situation.

EQUIPMENT

- Trauma shears*
- Gigli bone saw* (**Figure 95-1**)
- Several hemostats or Kelly clamps*
- Several trauma tourniquets*
- Scalpel*
- Medications for anesthesia, preferably procedural sedation* (Chapter 159)

TABLE 95-1 The Indications for a Prehospital Amputation

- An immediate and real risk to the patient's life due to a scene safety emergency.
- A deteriorating patient physically trapped by a limb and they will almost certainly die during the time taken to secure extrication.
- A completely mutilated and nonsurvivable limb retaining minimal attachment and delaying extrication and evacuation from the scene.
- The patient is dead and their limbs or body are blocking access to potentially live casualties.
- Extrication will not occur rapidly, the patient is hypotensive and the patient is considered a nonresponder to initial IV fluids (i.e., life before limb).
- Extrication will not occur rapidly and further structural collapse or bodily injury is imminent if they are not rapidly extricated.
- Extrication will be extended, the patient was initially hypotensive but responded to initial IV fluids, and the patient currently has an adequate blood pressure.
- The patient is hemodynamically normal and in the best judgment of the rescue personnel and field physician extrication is likely to take many hours if it can be done at all.

Source: Modified from references 12 and 13.

FIGURE 95-1. The Gigli saw.

- Sterile gloves
- Sterile gown
- Face mask
- Goggles
- Foot protection
- Vascular access (e.g., intravenous [IV] or intraosseous [IO])
- Sterile towels or drapes
- Povidone iodine or chlorhexidine solution
- Liston amputation knife
- Laparotomy pads
- Trauma dressings
- Bone wax
- Elastic bandage
- Mayo scissors
- Sterile saline or sterile water for irrigation
- Portable battery-powered oscillating bone saw (optional) (**Figure 95-2**)

The minimum equipment needed in an austere environment or a confined space is noted with an asterisk (*) in the above list and shown in **Figure 95-3**. It is not always possible to have the required equipment in an emergency. A field amputation has

FIGURE 95-2. The Stryker oscillating bone saw is battery operated and portable.

FIGURE 95-3. The minimum required equipment for the field amputation of an extremity. Clockwise from top left: anesthesia and analgesia (ketamine), Kelly clamps and/or hemostats, trauma shears, combat tourniquet, Gigli saw, and a scalpel.

been performed with equipment borrowed from firefighters.^{14,15} This includes a hacksaw, a reciprocating saw, or a specialized cutting tool (**Figure 95-4**). Rescue tools serve as acceptable alternatives to surgical equipment. A comparison of the classic Gigli wire bone saw with rescue service hacksaws, reciprocating saws, and hydraulic cutting tools was performed in a simulated prehospital amputation scenario on cadavers.¹⁴ All of the tools were capable of amputation in less than 2 minutes. Each technique had various benefits and drawbacks.

PATIENT PREPARATION

The conscious and oriented patient should be involved in the discussion regarding a potential prehospital amputation. Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedural care should also be discussed. It is sometimes the case that the Emergency Physician may be able to obtain written consent. Some Emergency Physicians may omit the signed patient consent and place in the procedure note a documentation such as the following: “The risks, benefits, and complications were described and discussed with the patient. They understood this and gave verbal consent for the procedure.” Have a witness also sign this if it was witnessed. Attempt to discuss the procedure with next of kin and obtain consent if the patient is unable to participate in the decision-making process. Two Emergency Physicians should agree on a consensus if no decision-maker is available for the unconscious or delirious patient. Advances in telecommunication technology have provided cellular phones and mobile videoconferencing. Such methods are available when a second Emergency Physician is only available remotely. A verbal discussion over a recorded line is ideal. A consensus agreement between the Emergency Physician and officer in charge of the scene will do if only one physician is present and no other physician is available. **Clearly document the decision-making process and attempts at consent.**^{6,7,10,13,16}

The subsequent extrication route should be preplanned prior to the field amputation procedure. Resuscitate the patient. The patient’s airway should be controlled but it should not be considered mandatory to intubate. This is especially true as space and equipment constraints may preclude airway management. Effective IV or IO access will allow for adequate analgesia, anesthesia, and fluid resuscitation. Ketamine has the ideal properties for a prehospital amputation. It

D

E

allows for analgesia, anesthesia, retention of airway reflexes, and retention of respirations (Chapters 12 and 159).

The Emergency Physician should be wearing a gown, gloves, and a face mask with an eye shield or goggles. Foot protectors are desirable. A face mask and eye protection will prevent a mucous membrane exposure if the contents spray out of the incision. The gown will protect clothing from contamination. The patient's injury may cause significant external hemorrhage with subsequent bloodborne exposure hazards throughout the rescue area.^{6,12,13}

Remove any overlying clothing or debris from the limb. Apply a tourniquet proximally on the affected limb. Crushing and entrapment forces to the deep vasculature often tamponade the hemorrhage. The tamponade is relieved during the field amputation. Note the time of the tourniquet application and write this on the limb or tourniquet. Some EMS protocols include dispatch notification of tourniquet application. The first responders have often exposed the affected limb and applied a tourniquet. Administer broad-spectrum antibiotics prior to the procedure if they are available and the patient has no allergies. The conditions in which the amputation will be performed are far from sterile (e.g., industrial machinery, rubble of a structural collapse, and mangled passenger compartment of a motor vehicle). Establish a sterile field as best as possible with sterile drapes and towels. This allows a safe area to place and prepare the necessary equipment. Gross decontamination is initially achieved using sterile

water or saline to remove particulate matter and debris. Perform an antiseptic cleaning with povidone iodine or chlorhexidine gluconate and allow it to dry.^{6,12,13}

TECHNIQUES

FIELD AMPUTATION

The general techniques remain the same regardless of the extremity involved or the level at which it is entrapped. The procedure may be scaled up or down depending on whether it is a phalanx or a proximal long bone involved in the entrapment. **All amputations in the prehospital environment are performed as guillotine amputations. The anatomic structures are transected in an axial plane as if a guillotine dropped onto the limb.**^{8,9,12,13,17,18} This is in contrast to a skin and soft tissue flap formed in the Operating Room for the purpose of forming a mature stump. The ultimate technique and equipment used may depend on what is available at the time of the emergency.

Perform the amputation as distally on the limb as possible to allow the best possible functional outcome for the patient. For example, a proximal humerus amputation provides far less function, even with a prosthesis, than a distal forearm amputation. Make sure the tourniquet is placed proximally on the limb and at least 5 cm

A

B

FIGURE 95-5. An example of a joint disarticulation. **A.** The level of the disarticulation. **B.** The disarticulation. (Used with permission from reference 15.)

(i.e., 2 inches) above the site of amputation. Tighten the tourniquet to stop blood flow into the limb. Place a second tourniquet if needed for continued hemorrhage from the limb prior to the amputation. Cut the skin and soft tissue with the scalpel or Liston amputation knife. The Liston amputation knife is more expensive than a scalpel, takes up more space than a scalpel, and is usually not available. Some patients may have a nearly complete traumatic amputation with only soft tissue remaining on the limb. Continue cutting in the same plane as the initial cut to transect any tendons, ligaments, and/or muscles. Keep cutting down to the bone. The procedure may require more than one scalpel because the blade quickly dulls. The Liston amputation knife provides the benefit of a double-edged knife with a greater cutting surface which is less likely to dull.

Use blunt dissection once the area around the bone has been transected. Insert a Kelly clamp behind the bone. Push the closed Kelly clamp behind the bone and through to the other side. Grasp a laparotomy pad with the clamps and pull it pull back through the wound. Allow approximately equal halves of the laparotomy pad to hang out from behind the bone. Use the laparotomy pad to pull proximal traction and expose the bone surface. Cut the bone with the powered oscillating bone saw, a Gigli saw, or another device. Use an assistant to apply a gentle downward stabilizing force on the limb while cutting the bone. Use trauma shears, Mayo scissors, or the scalpel to divide all remaining tissue of the limb in the same axial plane as the rest of the procedure.

Attention must now be paid to ensuring hemostasis. Clamp any large blood vessels identified with hemostats or Kelly clamps. **This redundancy will minimize hemorrhage if the tourniquet becomes dislodged.** The tourniquet will stop most blood vessel hemorrhage. The vascular matrix of the bone is not amenable to external pressure. Apply bone wax to the end of the transected bone surfaces in the amputation stump to decrease bleeding. Hemostatic agents may be effective to manage continued bleeding from the soft tissue, but this has not yet been described in the literature. Apply a sterile dressing to the stump. Secure the dressing in place.

FIELD DISARTICULATION

The general technique is similar to the technique for an amputation. **Perform the disarticulation at the most proximal joint above the injury and as distally on the limb as possible to allow the best possible functional outcome for the patient.** Make sure the tourniquet is placed proximally on the limb and at least 5 cm (i.e., 2 inches)

above the site of disarticulation. Tighten the tourniquet to stop blood flow into the limb. Place a second tourniquet if needed for continued hemorrhage from the limb prior to the disarticulation. Identify the joint line and mark it on the skin (**Figure 95-5A**). Cut the skin and soft tissue with the scalpel or Liston amputation knife. Continue cutting along the joint line to transect any tendons, ligaments, and/or muscles. The procedure may require more than one scalpel as the blade quickly dulls. Separate the limb at the joint (**Figure 95-5B**).

Attention must now be paid to ensuring hemostasis. Clamp any large blood vessels identified with hemostats or Kelly clamps. **This redundancy will minimize hemorrhage if the tourniquet becomes dislodged.** The tourniquet will stop most blood vessel hemorrhage. The vascular matrix of the bone will not bleed in a disarticulation. Hemostatic agents may be effective to manage continued bleeding from the soft tissue, but this has not yet been described in the literature. Apply a sterile dressing to the stump. Secure the dressing in place.

PEDIATRIC CONSIDERATIONS

The procedure for pediatric patients is largely unchanged from that of a bigger person. Some techniques may need to be slightly altered. Pediatric limbs are significantly shorter. Preserve as much length as possible and the growth plates. A disarticulation is preferred over an amputation. The pediatric limb allows for less space above the injury for tourniquet application. Commercially available tourniquets may not work on smaller children due to their length and width. Use an improvised tourniquet or a manual pediatric blood pressure cuff. Ensure the cuff has no air leaks prior to its application. Apply tape circumferentially around the cuff to ensure there is no dislodgement of the cuff. Apply a Kelly clamp to the cuff tubing to decrease any leakage from the cuff via the thumbscrew valve after inflation of the cuff. Proceed with the amputation or disarticulation procedure.

AFTERCARE

Promptly transport the patient to the closest hospital capable of managing the injuries. The Emergency Physician who performed the amputation should accompany the patient to the hospital to manage any ongoing bleeding or complications. Continuing patient care needs at the scene may require that the Emergency Physician stay behind (e.g., in the event of a mass casualty). Retrieve the

amputated limb if safe to do so. Place the limb in a bag covered with sterile dressings soaked in sterile saline. **Do not place the limb on ice as this may cause further tissue damage.** The reimplantation of the amputated extremity is unlikely. The decision is best left to the Surgeons at the hospital. The amputated extremity can be used at the very least for autologous skin grafting by the Surgeon when modifying the stump.^{6,12,13}

COMPLICATIONS

There is often little preparation of predefined Physicians or equipment prior to the sudden unexpected need for a field amputation.⁵ This can lead to the complications of hastily prepared equipment or unprepared surgical teams being deployed into a prehospital environment for the first time. There may be practical complications associated with the attempts to integrate hospital providers into a prehospital environment and the chain of command with no prior field experience. Hospital providers will need to be quickly briefed on safety concerns and risks on the scene. Various hazards to the hospital provider on the scene may include traffic awareness on a highway, bloodborne pathogens, unstable structures, safety around rescue tools, and safety when working in confined space environments.

There may be legal, cultural, or religious ramifications for amputations of living patients or the dismemberment of deceased victims. Early involvement of family and local leaders may aid in the decision-making process and long-term quality of life for the patient.⁶ Providers at the scene may endure psychological trauma from the severity of injury and the amputation procedure. Scene supervisors should assess health care providers for the need for further critical incident stress management.⁷

There are numerous complications associated with the procedure. Bleeding is possible with any prehospital amputation. Tourniquets should be checked multiple times to ensure they are well placed and adequately secured prior to the procedure and prior to the transport. Care must be taken to avoid dislodgement of the tourniquet when extricating the patient after the amputation. **Infection and gas gangrene of the wound are concerns.** Perform the procedure as cleanly as possible. A formal washout of the amputated extremity in the Operating Room is mandatory. Multiple revisions of the amputated stump will likely be required. Hemorrhagic shock and multisystem trauma are possible. Follow resuscitation protocols to minimize complications.¹³ Complications are common in survivors of field amputations. These include depression, loss of body image, loss of function, loss of independence, loss of mobility, loss of sensation, and the feeling of suicidal ideation. The patient may need psychiatric therapy for these issues.

The late complications can occur with any amputation no matter where it is performed (i.e., field or hospital). A bone spur often forms on the end of the amputated bone. This is usually painless but can cause an ulceration of the skin. The bone can become osteoporotic from disuse and easily fracture. The joint above the amputation may become deformed and stiff. A painful and tender neuroma may develop at the amputation site. Numerous conditions, including breakdown of the muscle and skin due to poor circulation, phantom limb feelings, and phantom limb pain can develop. The preservation of a life by performing the amputation is worth these complications.

SUMMARY

The field amputation of an entrapped extremity is a very low-frequency, high-acuity procedure that Emergency Physicians are generally ill-prepared to handle.⁵ A major EMS system may go years without a single prehospital amputation request, only to have several performed within a short time.⁷ Ensuring a predefined team with established protocols and prepared equipment will improve the chances

of a successful resuscitation and rescue of an entrapped patient. The presence of an Emergency Physician on scene directing the resuscitation, bringing additional medications, and bringing blood products may stabilize a patient long enough for a successful extrication without amputation. Familiarity with the anatomy, equipment, indications, and procedure will go a long way to reduce apprehension and improve outcomes if the need for a prehospital amputation is determined.

Extensor Tendon Repair

JoAnna Leuck and Keegan Bradley

INTRODUCTION

The Emergency Physician (EP) commonly encounters lacerations or trauma to the dorsum of the hand and forearm. **The possibility of extensor tendon lacerations must be considered in evaluating these patients.** A recent study found that tendon injuries in the hand and wrist occur at a rate of 33.2 injuries per 100,000

person-years, with extensor tendon injuries being the most common.¹ Single, shallow lacerations account for 54.4% of the tendon injuries studied and the most common location is the long finger.¹ The extensor mechanism of the hand and forearm is typically disrupted in association with penetrating trauma. Blunt trauma (e.g., sudden forced flexion) can result in injury to extensor tendons. Performing an extensor tendon repair is an important skill in the EP's surgical armamentarium.

The diagnosis of an extensor tendon injury must be identified during the initial examination. The timing of the tendon repair is not a critical aspect of its management. Successful repair of extensor tendons may be accomplished within a 7 day window following the injury.² Splint immobilization of the damaged tendon can produce a similar outcome to surgical reapproximation at some anatomic sites. Laceration of < 50% of any tendon in all zones that the patient can extend against resistance can be immobilized with early protected motion.³

Repair of an extensor tendon by an EP requires familiarity with the anatomy of the region and skill in the surgical technique. Complications of tendon repair are more frequently associated with flexor tendons. Follow-up studies of extensor tendon repairs reveal similar pitfalls and problems.⁴ Adhesions, loss of length, tendon rupture, Swan neck deformity, Boutonniere deformity, and diminished flexion can all complicate the repair of an extensor tendon.⁵

The anatomy of the extensor mechanism prevents tendon retraction far from the site of a laceration or partial disruption.⁶ This is mostly due to the tethering of tendons by multiple interconnections as tendons cross the dorsum of the hand. Tendons over the

dorsum of the hand are ensheathed in a paratenon layer of tissue. This covering is extrasynovial and contains the cut ends of tendons in a tissue layer that prevents their wide separation. These properties frequently allow both ends of a lacerated extensor tendon to be located with local wound exploration.

The techniques for extensor tendon repair originate in studies of flexor tendons. **The goal of extensor tendon repair is to restore tendon continuity and function while minimizing interference from the repair itself.** The suture techniques of Kessler and Bunnell are two of the methods traditionally used in this repair. Modifications of these original methods have resulted in the greatest outcome measurements of tendon strength.⁷ **Familiarity with these two suture techniques, knowledge of extensor tendon anatomy, and knowledge of surrounding structure anatomy is essential to the successful repair of any extensor tendon in the Emergency Department (ED).**

ANATOMY AND PATHOPHYSIOLOGY

The extensor tendon mechanism is an intricate system of pulleys and levers coursing along the dorsum of the forearm, wrist, and hand.⁸⁻¹¹ The function of these tendons is to extend the fingers and wrist from a flexed position. This finger motion is complemented by the actions of the intrinsic hand muscle groups (i.e., lumbricals and interossei).

The elegant anatomy of the hand extensor mechanism is best appreciated in diagrammatic representation (**Figure 96-1**). The forearm tendons pass through the extensor retinaculum of the wrist

FIGURE 96-1. The extensor tendons of the hand begin just proximal to the extensor retinaculum. After exiting from under this encasing sheath, the tendons form an interconnected network as they cross the dorsum of the hand.

FIGURE 96-2. The central extensor tendons of the digits are reinforced and aided by the lateral bands of the interosseous and lumbrical muscles. The extensor tendon is tethered to the joint surface by a sagittal band, which forms a protective hood. **A.** Lateral view. **B.** Superior view.

to travel across the dorsum of the hand to each of the fingers. The extensor tendons are reinforced in the fingers by the lateral bands of the intrinsic hand muscles to form a complex tendon that inserts onto the distal phalanx (**Figure 96-2**).

Knowledge of the anatomy of the extensor mechanism reveals certain salient points. The extensor retinaculum of the wrist is a complicated structure of fibrous canals through which the tendons pass and whose repair necessitates a Hand Surgeon's intervention. The paucity of soft tissue covering the dorsum of the hand makes extensor tendons quite vulnerable to penetrating trauma. The extensor tendons of the fingers are interconnected across the dorsum of the hand by the juncturae tendinum (**Figure 96-1**). This interconnection of tendons distributes the work of extension among the involved fingers. Redundancy is built into the extension of the first and small fingers with the presence of two separate extensor systems. An isolated tear of the extensor tendon of the index or small finger may not result in lack of function because of the contributing band from the extensor digitorum communis (**Figure 96-3**). There is great anatomic variability in the detailed distribution of these tendons.

The location of an extensor tendon injury is important in determining whether tendon repair in the acute ED setting is feasible. Eight zones define the location of an extensor tendon injury (**Figure 96-4** and **Table 96-1**). The zone chart was first described by Kleinert and Verdan to classify and organize the modes of repair.^{12,13} It is most commonly referred to as the Kleinert system. The odd-numbered zones refer to areas over the joints. The even-numbered zones refer to the bony areas. Any zone can experience injury and

FIGURE 96-3. Division of an extensor tendon in the dorsum of the hand may still allow for full finger extension because of the communicating juncturae tendinum.

undergo repair. The outcome is variable, depending on the suture technique and the mode of rehabilitation.

INDICATIONS

The decision to surgically repair a lacerated extensor tendon is multifactorial. One must consider the extent of the tendon laceration, the involvement of other tissues (e.g., bone or joint space), and the location of the tendon injury. Studies that define a minimum laceration width that requires tendon repair have not been performed. **It is generally accepted that a laceration greater than 50% of the tendon width requires surgical repair.**² A tendon that has a laceration less than 50% of its width will usually heal with conservative management. **One must put the finger through its entire range of motion to confirm normal function and movement of the affected tendon prior to making the decision as to whether conservative management is appropriate.** A lacerated tendon that is associated with significant overlying skin loss, joint space penetration, or a bony fracture will require repair by an Orthopedic or Hand Surgeon.

Defining the location of the tendon injury to the Kleinert zone system guides the decision of which tendons can be safely repaired in the ED. There are no published guidelines on whether these procedures should be performed at the bedside or in the Operating Room. A thorough understanding of the extensor tendon's anatomy and a good dose of common sense are imperative.

The following zones and types of injury represent sites where extensor tendon repair in the ED is feasible with minimal complications. The thickness of the extensor pollicis longus allows for a

FIGURE 96-4. The extensor tendons of the hand are easily classified by the Kleinert zone system. The odd numbers represent joint spaces. The even numbers represent long bones. Note that the thumb zones are distinct from the other digits.

core-type suture in zone 2 of the thumb. Repair of other zone 2 isolated injuries can be considered depending on the thickness of the tendon. The broad configuration of the extensor tendon allows for a core-type suture in zone 4 of all digits. Isolated involvement of the extensor tendon allows for a core-type suture unless the joint is involved in zone 5 of the fingers. Be alert for the possibility of zone 5 injuries being caused by a “fight bite.” Extensor tendon injury from a human bite should be copiously washed out and consultation with a specialist is required. Isolated involvement of the extensor tendon allows for a core-type suture and good prognosis in zone 6 of the hand.

CONTRAINDICATIONS

There are definite contraindications to repairing an extensor tendon in the ED. First and foremost is the lack of skill on the part of the EP. Performing this repair may result in loss of function or may further compromise the patient’s result. Consult an Orthopedic or Hand Surgeon if any doubt exists. Skin wounds can be closed loosely, the hand splinted, and the patient referred for delayed repair. Surgical repair of the tendon is not recommended if less than 50% of the tendon is lacerated and the finger functions as well as the corresponding finger on the unaffected opposite hand. The presence of a bony fracture, an open joint space, or the lack of adequate soft tissue or skin covering are contraindications to repairing an extensor tendon in the ED. **A tendon laceration from a human bite wound is an absolute contraindication to closure and repair of the injury.** The management and rehabilitation of these wounds necessitate

TABLE 96-1 The Characteristics of Injuries to the Zones of the Extensor Tendons

Zone	Characteristics
Zone 1	<ul style="list-style-type: none">• Disruption of terminal extensor tendon distal to or at the DIP joint of the fingers and IP joint of the thumb• Forceful flexion of the DIP joint with an extended finger• Open or closed• Flexion deformity over DIP joint• Often accompanied by a fracture resulting in a mallet finger• Can result in swan neck deformity if untreated
Zone 2	<ul style="list-style-type: none">• Disruption of tendon over middle phalanx or proximal phalanx of thumb• Results from crushing injury or lacerations
Zone 3	<ul style="list-style-type: none">• Disruption of central slip over the PIP joint of digit or MCP joint of the thumb• Open or closed• May be associated with a fracture• Often results in a Boutonniere deformity
Zone 4	<ul style="list-style-type: none">• Disruption over the proximal phalanx of digit or metacarpal of thumb• Lateral bands are spared
Zone 5	<ul style="list-style-type: none">• Disruption over MCP joint of digit or CMC joint of thumb• Commonly referred to as a fight bite• Rupture of the sagittal attachment• Usually open
Zone 6	<ul style="list-style-type: none">• Disruption over the metacarpals• Nerve and vessel injury
Zone 7	<ul style="list-style-type: none">• Disruption at the wrist joint• Must repair retinaculum to prevent complications (e.g., bowstringing)• Tendon repair followed by immobilization
Zone 8	<ul style="list-style-type: none">• Disruption at the distal forearm above the wrist• May involve the musculotendinous junction

CMC, carpometacarpal; DIP, distal interphalangeal; IP, interphalangeal; MCP, metacarpophalangeal.

consultation with the appropriate surgical specialist. Injuries to the thumb should be referred to a Hand Surgeon. Contraindications to immediate bedside repair by the EP are not wound-specific and include whether the patient has rheumatoid arthritis, is immuno-compromised, or is a professional athlete.

The Kleinert zone chart can be used to help determine the suitability of repairing an extensor tendon in the ED. The following zones on the forearm, wrist, and hand represent areas where wound care, skin closure, and splinting are highly recommended until an Orthopedic or Hand Surgeon can perform definitive surgical repair. Extensor tendon remnants may be too short in zone 1 of all digits. Extensor tendons of the fingers that are very thin in zone 2 should not be repaired except for those in the thumb. Actual or potential joint or lateral band involvement in zone 3 of all digits should not be repaired. Actual or potential joint or sagittal band involvement in zone 5 of all digits should not be repaired. Actual or potential extensor retinaculum involvement in zone 7 should not be repaired because of its complex anatomy. The actual or potential need for a tendon transfer in zone 8 requires an Orthopedic or Hand Surgeon. Patients discharged from ED with extensor tendon injury must have acute follow-up with an Orthopedic or Hand Surgeon whether primarily repaired or splinted.

EQUIPMENT

DIGITAL OR HAND ANESTHESIA

- Povidone iodine or chlorhexidine solution
- 10 mL syringe
- 25 to 27 gauge needle, 2 inches long
- 16 to 18 gauge needle
- Local anesthetic solution without epinephrine

■ EXTENSOR WOUND IRRIGATION AND PREPARATION

- 250 to 500 mL of sterile saline or Ringer's lactate solution
- Irrigation set
- 60 mL syringe
- 16 gauge angiocatheter
- Intravenous tubing
- Personal protective equipment
- Blood pressure cuff, preferably automatic
- Overhead lamp or source of intense lighting

■ EXTENSOR TENDON AND SKIN REPAIR

- Sterile surgical towels
- 4×4 gauze squares
- Forceps
- #11 blade disposable scalpel
- Needle driver
- Nonabsorbable, synthetic, and braided suture (e.g., 4-0, 5-0, and 6-0 Ethibond or Mersilene)
- Nylon suture (e.g., 4-0 and 5-0) for skin closure

■ WOUND DRESSING AND SPLINT

- Topical antibiotic ointment
- Gauze squares
- Elastic gauze bandage
- Splinting materials

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the planned procedure to the patient and/or their representative. The broad risks to the procedure include, but are not limited to, bleeding, infection, nerve damage, additional tendon damage, temporary or permanent stiffness, and a need for additional operations in the future. Alternative forms of therapy should be discussed. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Proceed with prepping and positioning the patient. Place the patient in a supine and comfortable position to minimize movement during the procedure. Place the involved hand on a bedside procedure table ideally at heart level so that the patient's arm is resting comfortably. Temporarily diminish arterial blood flow with a digital tourniquet or a blood pressure cuff applied to the arm if vascular bleeding is active and obscures the site of repair. Apply padding under the tourniquet. **The maximum tourniquet time should be less than 2 hours.**¹² Any surgical procedure that takes this long should not be performed in the ED. A Penrose drain can make an effective tourniquet for the finger (**Figure 96-5**). Other methods of finger hemostasis are discussed in Chapters 129 and 137.

Anesthesia to the affected area can be accomplished with a digital or wrist block (Chapter 156).¹⁴ The choice of procedure depends on the location and extent of the injury. Clean any dirt or debris from the hand. Apply povidone iodine or chlorhexidine solution and allow it to dry. Debride the wound and copiously irrigate it with 250 to 500 mL of sterile saline if no open joint is involved. The wound is now considered sterile. All techniques must be aseptic from this point forward. Apply sterile drapes or towels to delineate a sterile

FIGURE 96-5. The Penrose drain method to obtain digit hemostasis. Wrap the Penrose drain from a distal to proximal direction. Continue wrapping until the end of the digit is reached. Begin unwrapping the drain from distal to proximal to expose the laceration. (Photo courtesy of Keegan Bradley, MD.)

field. Place a sterile drape over the bedside procedure table. Lay out the required instruments and suture material on the bedside procedure table.

TECHNIQUES

Many techniques are used to repair lacerated tendons. All the original techniques were described referring to flexor tendons. These techniques have been expanded to include the repair of extensor tendons. Four common suture techniques used for a “core” repair of the extensor tendon include the mattress stitch, the figure-of-eight stitch, the modified Bunnell stitch, and the modified Kessler stitch (**Figure 96-6**).^{15,16} **No single stitch is optimal for any one zone of injury.** The type of stitch must be individualized based on the properties of the tendon at the site of injury. Evidence exists that the modified Kessler and Bunnell stitches produce the greatest strength for a core-type tendon repair (**Figures 96-6C and 96-6D**).⁷ These stitches may not be as well suited for extremely thin tendons (e.g., zones 4 or 6) as are figure-of-eight or mattress stitches (**Figures 96-6A and 96-6B**). The Bunnell and Kessler techniques are more useful in round and thicker tendons (e.g., flexor tendons or selected extensor tendons).^{7,17}

MODIFIED KESSLER STITCH

This “core” stitch is designed to place the direction of force perpendicular to the longitudinal axis of the tendon (**Figure 96-6C**). If the force of the suture is placed in the tendon's longitudinal axis, there is a tendency for the suture to pull through and shred the tendon.

Identify the two ends of the lacerated extensor tendon. **Handle the cut ends with maximal care. Blindly or bluntly grabbing the ends traumatizes tendons and compromises the repair.** A retracted tendon can be held in place with a needle piercing it perpendicularly.

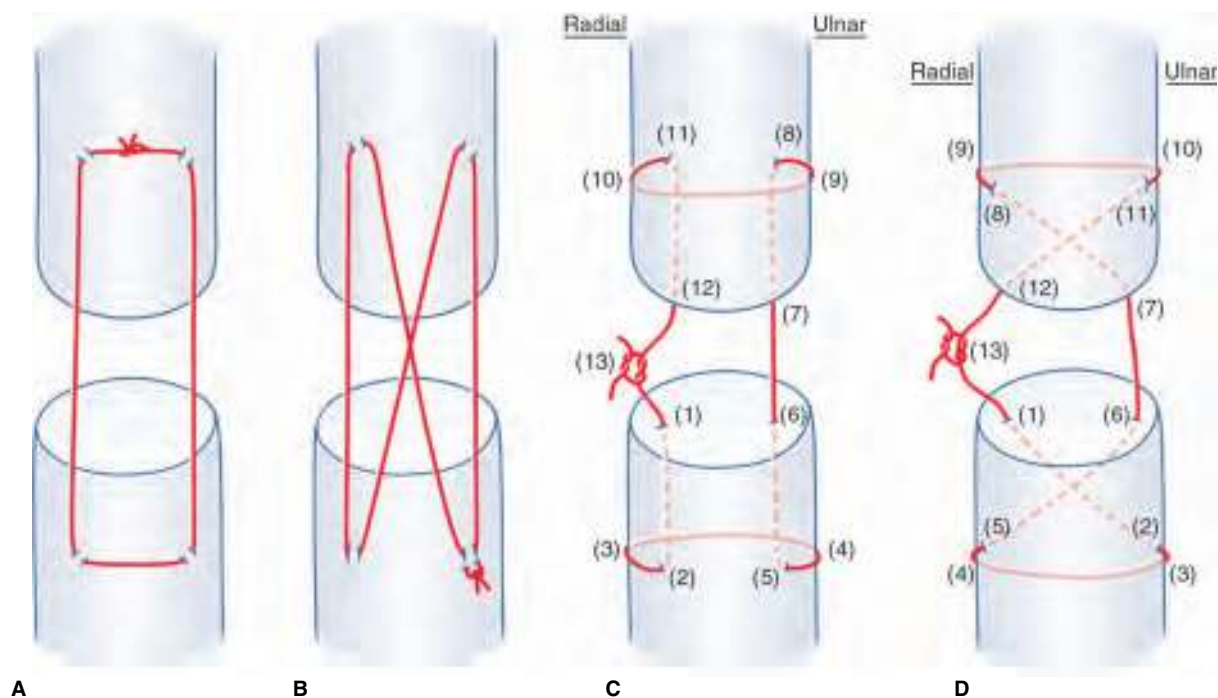

FIGURE 96-6. Suture techniques for extensor tendon repair. **A.** Mattress stitch. **B.** Figure-of-eight stitch. **C.** The modified Kessler stitch. The numbers represent the sequence of steps. **D.** The modified Bunnell stitch. The numbers represent the sequence of steps.

Judiciously debride the tendon ends if they are jagged or dirty. This can be performed with a fresh #11 blade scalpel cutting down against a wooden tongue depressor. **Do not remove too much length from the tendon.** Place the affected digit and wrist in maximum extension to facilitate approximation of the tendon ends.

Hold one end of the tendon gently with your fingers or a stitch. Introduce the needle into the cut end of the tendon (**Figure 96-6C-1**). The entrance point should be about one-third of the diameter of the tendon, beginning on either its ulnar or radial side. For simplicity, we begin on the radial side. Pass the suture approximately 1 cm through the length of the tendon and exit dorsally (**Figure 96-6C-2**). Wrap the suture around the tendon (**Figure 96-6C-3**). Reenter the radial side of the tendon perpendicularly and 1 to 2 mm closer to the tendon end (**Figure 96-6C-3**). Pull the suture straight through the tendon to exit on its ulnar side (**Figure 96-6C-4**). Wrap the suture around the tendon (**Figure 96-6C-5**). Enter the dorsal aspect of the ulnar half of the tendon (**Figure 96-6C-5**). This entrance stitch must line up with the first dorsal stitch (**Figure 96-6C-2**). Pass the needle through the length of the tendon to exit the end of the tendon (**Figure 96-6C-6**). The needle must exit on the ulnar one-third of the tendon.

Repeat the same stitch on the opposing piece of the tendon. Pass the needle into the ulnar one-third of the tendon (**Figure 96-6C-7**). Pass the suture approximately 1 cm through the length of the tendon and exit dorsally (**Figure 96-6C-8**). Wrap the suture around the tendon (**Figure 96-6C-9**). Reenter the ulnar side of the tendon perpendicularly and 1 to 2 mm closer to the tendon end (**Figure 96-6C-9**). Pull the suture straight through the tendon to exit its radial side (**Figure 96-6C-10**). Reenter the dorsal aspect of the radial half of the tendon (**Figure 96-6C-11**). The stitch must line up with the previous dorsal stitch (**Figure 96-6C-8**). Pass the needle through the length of the tendon to exit the end of the tendon (**Figure 96-6C-12**). The needle must exit on the radial one-third of the tendon.

The two free ends of the suture should be on the radial side of the tendon. Apply tension to the two free ends of the suture to gently

approximate the ends of the lacerated tendon. **Do not apply so much force that the ends bunch up.** Secure the stitch with a knot that will remain buried between the tendon ends (**Figure 96-6C-13**).

MODIFIED BUNNELL STITCH

This stitch follows the same principle as the Kessler stitch. It incorporates a crossing of the suture in its pathway (**Figure 96-6D**). Minimize the handling of the tendon in performing this stitch. **Instrumentation of the tissue is detrimental to its nutritional supply and can lead to adhesions.** One should ideally immobilize the tendon ends with one's fingers or a single suture.

Enter the tendon end on the radial half and at approximately one-third of the diameter of the tendon (**Figure 96-6D-1**). Pass the needle diagonally through the tendon and exit on the ulnar side (**Figure 96-6D-2**). Wrap the suture around the tendon (**Figure 96-6D-3**). Reenter the tendon on its dorsal half (**Figure 96-6D-3**). Pass the needle directly through the tendon to exit the dorsal surface of the radial aspect of the tendon (**Figure 96-6D-4**). Enter the radial side of the tendon (**Figure 96-6D-5**). Cross the suture diagonally through the tendon to exit its ulnar end (**Figure 96-6D-6**). The needle must exit through the ulnar one-third of the tendon end.

Repeat the same stitch on the opposing piece of the tendon. Pass the needle into the ulnar one-third of the tendon (**Figure 96-6D-7**). Pass the needle diagonally through the tendon and exit on the radial side (**Figure 96-6D-8**). Wrap the suture around the tendon (**Figure 96-6D-9**). Reenter the tendon on its dorsal half (**Figure 96-6D-9**). Pass the needle directly through the tendon to exit the dorsal surface of the ulnar aspect of the tendon (**Figure 96-6D-10**). Wrap the suture around the tendon (**Figure 96-6D-11**). Enter the ulnar side of the tendon (**Figure 96-6D-11**). Cross the suture diagonally through the tendon to exit the radial end of the tendon (**Figure 96-6D-12**). The needle must exit through the ulnar one-third of the tendon end.

The two free ends of the suture should be on the radial side of the tendon. Pull gently on the suture ends to approximate the ends of the lacerated tendon. **Do not apply so much force that**

the ends bunch up. Secure the stitch with a knot, which will remain buried within the tendon ends (**Figure 96-6D-13**).

AFTERCARE

Close the overlying skin with nylon suture, ideally everting the skin edges with a horizontal mattress suture. Apply topical antibiotic ointment. Apply 4×4 gauze squares to cover the wound. Apply an elastic bandage for protection. Splint the extremity to immobilize the repaired tendon and its associated muscle belly.

The patient may be discharged home with follow-up arranged within 24 to 48 hours with an Orthopedic or Hand Surgeon. Instruct the patient to elevate the extremity. They should return to the ED immediately if there is increased pain, numbness, or tingling in the digits; if the digits become cold or blue; or if a fever develops. Pain can be controlled with nonsteroidal anti-inflammatory drugs (NSAIDs) supplemented with an occasional narcotic analgesic. Many physicians prescribe prophylactic antibiotics. There is little evidence supporting this practice.¹⁸

Static immobilization may not be the optimal postoperative management for extensor tendon repairs. The affected tendon may benefit from early mobilization exercises or dynamic splinting depending on the zone of injury. Dynamic extension splinting may produce fewer complications and less postoperative adhesions.¹⁹⁻²¹ Tendon injuries in zones 1 to 4 can be temporarily immobilized in extension until follow-up by an Orthopedic or Hand Surgeon determines definitive splinting management. Tendon injuries in zones 5 to 8 can be placed in a temporary static splint with the wrist in 30° of extension, the metacarpophalangeal joints in 15° of flexion, and the interphalangeal joints in full extension.

The aftercare of extensor tendon lacerations necessitates close follow-up by an Orthopedic or Hand Surgeon for the evaluation of tendon function, wound evaluation, and rehabilitation strategies.²²

Proper aftercare and hand rehabilitation are crucial to ensure successful results of a tendon repair.²² The rehabilitation and recovery are different than those in children.²³

COMPLICATIONS

Surgical repair of any open wound or tendon laceration can result in unforeseen infections. Careful instructions for wound care and follow-up evaluations are important for early detection and treatment of tissue infection. The use of sterile technique and copious irrigation before tendon repair will minimize infections.

Failure of the tendon repair can be due to several etiologies.²⁴ Disruption of the surgical repair, the formation of adhesions, and joint stiffness can produce an inadequate outcome.²⁵ It is rare to encounter these complications in the ED. Nonetheless, they are real complications that both the EP and patient must discuss before proceeding with the repair procedure.

SUMMARY

The repair of an extensor tendon laceration can and does occur in the ED. The literature and authors have found that the use of the Bunnell and Kessler stitches for repair of extensor tendon injuries produce good results. The mattress technique and figure-of-eight stitch may be more useful for repair of thinner extensor tendons. Effective communication with an Orthopedic or Hand Surgeon is imperative in optimizing patient outcomes. The wound must be irrigated, explored, closed, and appropriately splinted for delayed surgical repair by an Orthopedic or Hand Surgeon. Postoperative rehabilitation is crucial to ensure an optimal outcome. Splinting in the ED should only be a temporizing immobilization procedure until rehabilitation therapy occurs.

Arthrocentesis

Eric F. Reichman, John Larkin, and Brian Euerle

INTRODUCTION

Arthrocentesis is the insertion of a needle into a joint cavity for the removal of synovial fluid and/or the injection of pharmaceutical agents into the joint cavity. Fluid can be aspirated from almost any joint. Arthrocentesis is used to diagnose and make treatment decisions regarding a joint. Obtaining synovial fluid is safe, simple,

relatively pain free, inexpensive, and extremely beneficial to the patient.

Arthrocentesis may be diagnostic or therapeutic.¹ Diagnostically, it is performed to identify the cause of an acute arthritis, to identify an intraarticular fracture, to identify the causes of an effusion, or to give a therapeutic trial of pharmaceuticals. It can also be therapeutic by relieving pain from elevated intraarticular pressure, to drain septic or crystal-laden fluid, or to inject pharmaceuticals. Ultrasound (US)-guided joint aspiration is a supplemental technique that improves several aspects of the arthrocentesis procedure.

Synovial fluid analysis will provide unique and valuable information about the affected joint.^{2,3} It is the only method to definitively diagnose or rule out a septic arthritis.^{4,5} The fluid should be analyzed for the presence of crystals. A white blood cell count and differential may help identify the causes of an effusion. A Gram's stain can be quickly performed to identify bacteria in the synovial fluid. Bedside gross analysis of the fluid's physical properties such as clarity, viscosity, and color has been shown to be a reliable clinical predictor of a potentially septic joint.⁶ A culture of the synovial fluid should be performed to definitively identify any microbiologic pathogen in the joint.

There are several general principles that should be followed when performing an arthrocentesis (**Table 97-1**). The Emergency Physician (EP) must know the anatomic relationships around the joint. The needle should go around and not through any tendons. Avoid piercing the articular cartilage, which is avascular and may not heal. Do not bounce the needle off the bone, as this is extremely painful for the patient. Insert the needle through the extensor surface of the joint. The synovial cavity is closest to the skin over the extensor surface of the joint. The extensor surface has fewer tendons and ligaments than the flexor surface. Most of the blood vessels and nerves are located on the flexor surface of the joint. Using the extensor surface of the joint for the procedure will avoid potential injury to these structures. Place the joint in slight flexion to maximize the size of the joint cavity. Apply distal in-line traction to the small joints of the wrists, hands, and feet to enlarge the joint cavity. This allows the needle to more easily enter the small joint spaces. Compression of large joints will mobilize peripheral fluid. This is helpful when the volume of synovial fluid is small. Compression may be applied manually or with an elastic bandage.

It is critical to use sterile technique to prevent the infection of a nonseptic joint as well as to ensure the joint fluid is uncontaminated for microbiological cultures. Sterile drapes, sterile gloves, and face masks are not needed to perform the procedure.⁷⁻⁹ It is necessary to wear gloves to prevent transmission of bloodborne diseases to the EP.^{7,10} The skin should be cleansed and prepped in the usual manner. The needle may then be grasped, with clean gloves, at the hub and inserted. As long as the skin and needle are not handled, sterile gloves are not required. This is sometimes difficult to master

if the EP has little practice with the technique of arthrocentesis. It may be better to err on the side of conservatism and use sterile gloves and drapes, particularly with inexperienced EPs and in training situations.

US has been used by EPs, Interventional Musculoskeletal Radiologists, and Rheumatologists to guide needles for joint injections and aspirations.¹¹⁻¹⁶ US guidance allows these procedures to be performed in a safer manner because the needle is less likely to injure nerves, tendons, and blood vessels. US also allows a comparison with the asymptomatic opposite-side joint. As bedside ultrasonography has become used more commonly in the ED, more EPs are appreciating and reporting on its benefits of guiding arthrocentesis.¹⁷⁻²¹ Arthrocentesis is commonly performed on the shoulder, elbow, hip, knee, and ankle joints. It may also be performed on other joints. US guidance can be a useful adjunct in all of these procedures.

There are several possible approaches for the use of US-guided arthrocentesis in the ED. Knee arthrocentesis is commonly performed with a high success rate using the landmark-palpation technique. Many EPs feel comfortable performing this procedure without the routine use of US guidance. Wiler and colleagues compared US-guided versus standard landmark techniques for knee arthrocentesis and found that US guidance did not improve overall success.²¹ Other EPs use US guidance in cases anticipated to be difficult, such as in patients with small effusions or those with prior joint surgery. Some EPs feel that US guidance improves the safety of arthrocentesis and thus choose to use it whenever an arthrocentesis is performed. This approach is especially appealing in light of the fact that US is noninvasive and does not add any risk to the procedure.

INDICATIONS

Arthrocentesis is indicated to evaluate the cause of an arthritis or a joint effusion (**Table 97-2**).^{10,22-24} All patients presenting with an acute monoarthritis or an acute nontraumatic effusion should undergo arthrocentesis when the diagnosis is not clear based on the history and physical examination. Analysis of the synovial fluid is essential to help differentiate inflammatory from noninflammatory causes of joint disease. **Arthrocentesis is the only reliable method to confirm the presence of an infectious agent as the cause of an arthritis.** The presence of crystals within the synovial fluid can diagnose gout or pseudogout from other crystal-induced arthritides. **Always keep in mind that two or more types of arthritis can coexist in a patient or in a single joint.¹⁰**

Arthrocentesis may be therapeutic.²⁵ A large effusion, regardless of the cause, stretches the joint capsule, causing pain and limiting range of motion. Removal of the fluid will decrease pain and increase the joint's range of motion. An effusion caused by inflammation or sepsis contains numerous mediators of inflammation. Removal of this synovial fluid will help to relieve the patient's discomfort. The removal of purulent fluid will decrease the number of

TABLE 97-1 General Principles for Arthrocentesis

- Know the anatomic relationships
 - Avoid piercing any tendons
 - Do not damage articular cartilage
 - Do not penetrate bone
- Use sterile technique
- Provide adequate analgesia
- Place the joint in slight flexion
- Apply distal traction to small joints
- Apply compression to large joints
- Enter the extensor surface
- Use US guidance if available

TABLE 97-2 The Indications for Performing an Arthrocentesis

- To evaluate a monoarticular arthritis
- To diagnose and treat a traumatic arthritis
- To diagnose an intraarticular fracture
- To diagnose an intraarticular ligamentous disruption
- To relieve pain
- To diagnose inflammatory versus noninflammatory disorders
- To identify the cause of an effusion
- To rule out an infection
- To identify a crystal-induced arthritis
- To inject therapeutic agents

organisms in the joint cavity and, theoretically, may limit further joint destruction.²⁶

Injection of therapeutic agents into nonseptic joints is commonly performed in the Emergency Department (ED). Local anesthetic solutions may be injected to relieve pain. A joint examination after trauma may be limited secondary to pain. Injection of local anesthetic solutions can relieve pain and allow an examination for ligamentous and joint instability. Corticosteroids are injected into joints to control inflammation and arthritis pain. Sometimes, corticosteroids and local anesthetic solutions are combined into one syringe and injected intraarticularly. The local anesthetic provides immediate pain relief and assures the EP of proper needle placement. However, there are downsides. **Local anesthetic agents should be used sparingly as they may have chondrotoxic effects.²⁷⁻²⁹ As with anything we do, we must weigh the benefits versus the risks.**

Arthrocentesis can be used to diagnose and treat traumatic arthritides. The traumatic event is usually acute, obvious, and followed by joint pain and swelling. Occasionally, the trauma is minimal or remote and not recalled by the patient. A traumatic effusion can be grossly bloody and, if acute, may contain a large amount of red blood cells. **The bloody synovial fluid represents an intraarticular fracture or a disruption of an intraarticular structure.³⁰** An intraarticular fracture may be suspected based on mechanism of injury and yet radiographic findings may be negative. The synovial fluid may then be evaluated for fat globules, which are released from the marrow cavity of the fractured bone, which confirm the presence of an intraarticular fracture.

The temporomandibular joint is a highly specialized joint that has a unique set of problems associated with it. Arthrocentesis can be an easy, minimally invasive, and efficient procedure used to solve some of these issues. Degenerative joint disease and joint lock are two examples of conditions that are amenable to therapeutic arthrocentesis, although much debate still exists concerning efficacy and therapeutic value of this procedure.

CONTRAINDICATIONS

There are no absolute contraindications to arthrocentesis. All contraindications are relative. The risks and benefits of the procedure should be evaluated and a decision made with the informed consent of the patient. **If a septic joint is suspected, it should be aspirated despite the presence of any relative contraindication. The benefit of the procedure outweighs any relative contraindication when compared to the morbidity of an undiagnosed septic arthritis.**

The presence of a suspected or known skin cellulitis, or other infection overlying the joint, is a relative contraindication. A dermatitis or skin lesion overlying the joint should also be avoided. The skin or subcutaneous tissue can harbor organisms that may contaminate the joint when the needle passes through the dermatitis or skin lesion. Often, an alternative site can be found to perform the arthrocentesis and avoid the above obstacles. If the needle is inserted into the joint through any potential or obvious source of infection, antibiotic treatment is required due to the theoretical risk of introducing an infection into the joint cavity.²² In these cases, patients should be placed in observation for 23 hours of intravenous antibiotics with a spectrum that covers skin flora.

Infections after arthrocentesis, in previously sterile joints, have been reported in bacteremic patients.²² It is not clear whether the source of the septic arthritis was from the arthrocentesis or bacteremia coincidentally seeding the joint. It is recommended to avoid arthrocentesis in any patients with bacteremia or sepsis except to rule out a septic arthritis.³¹

Patients may be coagulopathic due to pharmacologic therapy, factor deficiencies, liver dysfunction, or many other causes. When possible, the coagulopathy should be reversed prior to arthrocentesis.

Unfortunately, this is not always possible or practical. An experienced EP can safely perform the procedure without reversing the coagulopathy. Use the smallest needle gauge possible (22 or 23 gauge) to aspirate the joint fluid. Avoid injury to the articular cartilage by identifying the anatomic landmarks prior to the procedure. Do not bounce the needle off any bony surfaces.

The procedure may be difficult in some patients. In the morbidly obese, it may be difficult to identify anatomic landmarks. The standard needle may be too short to enter the joint cavity. A spinal needle may be required to perform an arthrocentesis in an obese patient. Uncooperative patients require sedation and/or restraint prior to performing the procedure.

A prosthetic joint or an arthroscopic procedure increases the risk of a septic arthritis.³²⁻³⁵ Arthrocentesis is technically more difficult secondary to scar formation and alteration of the normal anatomic relationships. **Joints that contain a prosthesis should be aspirated only to rule out a septic arthritis. Arthrocentesis for other reasons, including joint injection, should be referred to a consultant.**

Corticosteroids are instilled into joints for a variety of conditions. If the patient has no response to the injection within a few weeks, it may be repeated. If multiple injections cause no improvement, an alternative form of therapy should be explored.^{36,37} Multiple injections into a joint increase the risk of complications.

EQUIPMENT

- Clean or sterile gloves
- Gauze squares
- Povidone iodine or chlorhexidine solution
- Sterile skin marking pen
- Local anesthetic (e.g., injectable, vapor coolant, or ice)
- 25 to 27 gauge needle
- 3 mL syringe
- Needles to aspirate fluid (18/20/22 gauge)
- Syringes to aspirate fluid (1/3/5/10/20/30/60 mL)
- Hemostat
- Specimen tubes
- Culturettes or culture tubes

OPTIONAL EQUIPMENT

- US machine
- US gel
- US transducers (5 to 10 MHz)
- Sterile US transducer covers

Arthrocentesis should be performed with a needle of sufficient bore to allow the aspiration of thick fluid, fluid with debris, or purulent fluid. An 18 to 20 gauge needle is recommended for large joints (e.g., shoulder, elbow, ankle, knee, and hip). A 22 to 23 gauge needle is recommended for all other joints. Using too small a needle makes the procedure technically more difficult and more painful for the patient.

A high-frequency (5 to 10 MHz) linear array transducer is preferred for arthrocentesis and should be used whenever possible.¹¹ If this type of transducer is not available or if more depth of field is required, a curvilinear array may be used. Cavalier and colleagues described the use of color Doppler and a sterile needle guide attached to the transducer when performing US-guided arthrocentesis in children.³⁸ Doppler was used to localize the blood vessels

so that they could be avoided by the needle. While Doppler may occasionally provide additional anatomic information, it is not used routinely when performing an arthrocentesis. The use of a needle guide depends on the personal preference of the sonographer.

PATIENT PREPARATION

A complete history and physical examination should be performed prior to the arthrocentesis. The affected joint should be thoroughly assessed. Inspect the skin overlying the joint for breaks, infection, old scars, prior incisions, superficial lesions, or any wounds. Palpate the joint to identify any warmth, tenderness, or effusion. Evaluate the joint for any crepitation, deformity, ligamentous instability, or limitations in motion.

As with any nonemergent procedure, consent should be obtained from the patient or their representative. Ideally, the consent should be documented in the medical record and signed by the patient. Some prefer to note on the patient's chart "indications, risks, and benefits were discussed with the patient" rather than having the patient sign a consent form.^{10,39} The following is a sample consent for performing an arthrocentesis (which may be written on the medical record and signed by the patient):

Arthrocentesis involves inserting a small needle into your _____ joint. The skin is anesthetized prior to the procedure. Ordinarily, the procedure has no significant complications. Occasionally, a patient may experience bleeding into the joint, infection of the joint or skin, pain, bruising, nerve injury, or an allergic reaction to the medications administered. These complications are minimized by the use of sterile technique and proper techniques.

Position the patient based on the specific joint to be aspirated and the approach to be used. Expose the joint and surrounding areas. Identify the anatomic landmarks required for proper needle placement. The landmarks may be difficult to identify on a swollen and tender joint. Compare the "affected" joint to the "normal" joint on the opposite side of the body. Identify the joint and a landmark on the normal joint and transfer this to the affected joint. Clean any dirt and debris from the skin. Scrub the needle insertion site with povidone iodine or chlorhexidine solution and allow it to dry.

Apply anesthesia to the skin and subcutaneous tissue using 1% lidocaine, topical vapor spray, or ice.⁴⁰ The administration of some form of local anesthesia is recommended but not required.^{10,41} The most common local anesthetic used is a short-acting injectable anesthetic solution of 1% lidocaine. **Do not inject the local anesthetic solution deeper than the subcutaneous tissues.** Deep injections may instill anesthetic solution into the joint cavity which may interfere with the synovial fluid analysis. There is disagreement regarding whether the additional needlestick to administer the anesthesia causes as much discomfort as aspiration without any anesthesia. This decision is specific to each patient and EP.
